24 **Abstract**

25

26 A combined experimental and numerical study on the variation of the elastic properties of

27 defective single-crystal diamond is presented for the first time, by comparing

28 nano-indentation measurements on MeV-ion-implanted samples with multi-scale modeling

29 consisting of both *ab initio* atomistic calculations and meso-scale Finite Element Method

30 (FEM) simulations. It is found that by locally introducing defects in the 2×10^{18} - 5×10^{21} cm^{-3}

31 density range, a significant reduction of Young's modulus, as well as of density, can be

32 induced in the diamond crystal structure without incurring in the graphitization of the

33 material. *Ab initio* atomistic simulations confirm the experimental findings with a good

34 degree of confidence. FEM simulations are further employed to verify the consistency of

35 measured deformations with a stiffness reduction, and to derive strain and stress levels in the

36 implanted region. Combining these experimental and numerical results, we also provide

37 insight into the mechanism responsible for the depth dependence of the graphitization

38 threshold in diamond. This work prospects the possibility of achieving accurate tunability of

39 the mechanical properties of single-crystal diamond through defect engineering, with

40 significant technological applications, i.e. the fabrication and control of the resonant

41 frequency of diamond-based micromechanical resonators.

42

1. Introduction

45

46   Diamond is an extremely attractive material for a broad range of technological

47   applications due to its unique physical and chemical properties. In particular with regards to

48   its extreme mechanical and thermal properties, in the past years several works were focused

49   on developing mechanical structures and resonators in diamond either by MeV ion

50   implantation [1, 2] or by reactive ion etching [2-6] with the purpose of taking advantage of its

51   high mechanical hardness, stiffness and thermal conductivity. Moreover, diamond hosts a

52   wide variety of luminescent defect centres [7, 8] that can act as stable single photon emitters

53   at room temperature or as optically addressable solid-state spin-qubits [9, 10]. A challenging

54   goal in this field is to efficiently couple negatively charged nitrogen-vacancy centres to

55   resonant mechanical structures [11-13]. For advanced applications in nano-opto-mechanical

56   devices, the prospect of being able to modify and finely tune the mechanical properties of

57   diamond is therefore particularly appealing. In the case of other "2-D" carbon-based

58   materials (e.g. carbon nanotubes or graphene), the effect of structural defects on their

59   macroscopic mechanical properties has been studied both experimentally [14, 15] and

60   theoretically [16, 17], while a significant gap is present in the case of bulk diamond. Here, we

61   report such a systematic study, showing that a controlled modulation of the Young's modulus

62   of diamond can be effectively achieved by defect engineering through MeV ion irradiation.

63   Ion beam lithography based on MeV [18-20] or keV ions [21, 22] has emerged in the past

64   years as one of the most promising techniques used in the micro- and nano-machining of

65   diamond for different applications. It is known that ion implantation induces structural

66   modifications (at low damage densities, consisting primarily of vacancies and interstitials

67   [23]) and local mass density variations in the diamond crystal, which in turn result in

68   mechanical deformations, including surface swelling [24] and local stresses [25, 26]. A

69   mixed analytical/numerical approach to estimate these stresses has been developed, providing

70   good agreement with experimental measurements [27]. One important issue that remains to

71   be adequately addressed, however, is the variation of the elastic properties of damaged

72   diamond as a function of induced damage density. This is particularly relevant for the

73   Young's modulus, which is expected to vary between that of pristine diamond (i.e. ~1135

74   GPa [28, 29]) and that of amorphous carbon (i.e. ~20 GPa in a fully amorphized phase [30]).

75   Clearly, this large variation in elastic properties is likely to strongly affect the modeling of

76   implantation-induced stresses. Attempts have been made to experimentally derive the

77   variation of elastic properties in irradiated diamond [26], but only indirect estimations with

78   limited accuracy were obtained. This significant lack of experimental evidence is partly due

79   to the extremely high Young's modulus value of the pristine material, which makes it

80   difficult to probe its mechanical properties. A related open question is represented by the

81   relatively high uncertainty found in the literature on the value of the so-called "amorphisation

82   threshold" of diamond, i.e. the damage level (usually parameterized with a vacancy density,

83   as calculated via the SRIM Monte Carlo code [31]) above which the diamond lattice is

84   permanently amorphized, and subsequently graphitizes upon thermal annealing. It is often

85   hypothesized that the large variability of this parameter is related to the depth of implantation

86   [32], as well as to self-annealing effects [33], but so far no unequivocal evidence of these

87   effects has been provided.

88   In this work we present the first systematic study of the controlled variation of the

89   elastic properties of diamond as a function on induced structural damage. The experimental

90   measurements of the Young's modulus of MeV-ion-implanted diamond are performed with

91   the nano-indentation technique and results are complemented by numerical simulations at

92   two different scales, i.e. *ab initio* atomistic calculations of defected diamond supercells and

93   Finite Element Method (FEM) simulations of full-field deformations and stresses at the

94   meso-scale. Besides allowing a new level of control in the fine-tuning of mechanical

95   properties of diamond-based mechanical structures, our analysis also allows a novel

96   interpretation for the depth dependence of the amorphization threshold based on rigorous

97   continuum mechanics considerations.

98

2. **Experimental**

100   *2.1. Sample preparation*

101   The sample under investigation was an artificial HPHT type Ib single crystal diamond

102   sample synthesized by Sumitomo (Japan), $3\times3\times0.3$ mm^3 in size, cut along the (100)

103   crystalline direction with four optically polished faces: two opposite large surfaces and two

104   opposite lateral surfaces. These "mechanical grade" diamond samples typically contain

105   various impurities (N, Fe, Ni, Co) at concentration levels of the order of ~10-100 ppm, which

106   do not affect significantly their mechanical properties, as confirmed by the test measurement

107   performed from undamaged regions. The sample was implanted at room temperature on one

108   of its lateral polished faces across its edge with one of its large surfaces, as schematically

109   shown in Fig. 1, using a 2 MeV H$^+$ ion microbeam at the INFN Legnaro National

110   Laboratories. A rectangular area of approximately 100×200 μm^2 was raster-scanned to

111   deliver a uniform implantation fluence of 1×10^{17} cm^{-2}.

112   SRIM simulations were carried out using the SRIM 2012.03 Monte Carlo code [31] to

113   estimate the linear damage profile $\lambda(x)$, expressed as the number of induced vacancies per

114   incoming ion per unit depth x. The calculations were carried out in "Detailed calculation

115   mode with full damage cascade" mode, by setting the atom displacement energy value to 50

116   eV [34]. According to simulations, the irradiation conditions generate a strongly

117   inhomogeneous damage density profile peaked at a depth of ~25 μm from the surface (see the

118   inset of Fig. 1).

119

120   *2.2. Raman characterization*

121   Micro-Raman spectroscopy was employed to assess the degree of

122 amorphization/graphitization in the regions of the diamond sample which were characterized

123 by the highest ion-induced damage density, i.e. in correspondence with the end-of-range

124 Bragg peak. The measurements were performed in the same cross-sectional geometry

125 adopted for the nanoindentation measurements, i.e. the probing laser beam was focused

126 across the upper surface of the sample and scanned across the ion-beam-induced damage

127 profile (see Fig. 1). A similar approach has been adopted in previous Raman studies in ion-

128 implanted diamond [32, 35]. An inVia Raman micro-spectrometer (Renishaw) was employed,

129 with a $\lambda = 514$ nm excitation laser beam focused onto a micrometric spot with a 80× objective.

130 The laser power focused on the probed region was ~2.5 mW. A PC-controlled stage allowed

131 the sample displacement across the three directions, and thus the mapping of the Raman

132 signal with micrometric resolution. Results are reported in Section 4.1.

133

134   *2.3. Nanoindentation measurements*

135   The lateral implantation geometry shown in Fig. 1 enabled to gain access to the upper

136 surface of the sample with a nano-indentation profilometer, and thus a direct measurement of

137 the structural and mechanical properties (i.e. hardness and Young's modulus) of the damaged

138 diamond for a varying vacancy density profile. The choice of energetic light ions offered the

139 advantage of inducing a relatively broad damage profile, so that the nanoindentation

140 measurements were not influenced by edge effects. The nanoindentation measurements were

141 carried out with a Hysitron TI 950 TriboIndenter, allowing high spatial resolution down to

142 500 nm and the probing of ultra-hard materials such as diamond thanks to the large applied

143 loads 5000 µN. The instrument is equipped with *in situ* Scanning Probe Microscopy (SPM)

144   imaging capability, using a Berkovich tip. The first step of the measurement consisted in the

145   acquisition of a large-area SPM topography map, to determine the location of the Bragg peak

146   and the corresponding swelling [36]. A Scanning Probe Microscopy (SPM) mapping of the

147   measured region is shown in Fig. 2(a), highlighting a line along which a profile was acquired,

148   from the sample edge to the bulk. The topography maps were acquired using the nano-

149   indenter Berkovich tip in contact mode with a set-point of 2 µN and with scan rate of 1 Hz,

150   and a scan size of 50×50 µm^2. A profile related to an unimplanted region near the indentation

151   line was subtracted from the SPM curves, to eliminate effects related to sample tilt, thermal

152   drift and nonlinearity of piezo-electric actuators. A 20×20 µm^2 map was then acquired in the

153   proximity of the peak and nano-indentation was performed in the same region. The

154   indentation profile was realized with 72 indents at a distance of 250 nm, resulting in a total

155   profile length of 18 µm. A load of 5 mN was applied at a rate of 0.5 mN s^{-1}, applying the

156   maximum load for each indentation for 2 s. In correspondence of every indent, "load vs

157   displacement" curves were acquired, from which the elastic modulus of the material was

158   derived using the approach proposed by Oliver and Pharr [37]. Indentation measurements

159   were performed in the linear elastic range, both in unimplanted and in ion-implanted areas.

160   As an example, Fig. 2(b) reports loading and unloading force-displacement curves collected

161   from unimplanted (dashed black curve) and implanted (solid blue curve) regions of the

162   sample, with the latter measurement taken in correspondence with the implantation Bragg

163   Peak. Loading and unloading curves coincide, showing that test are carried out in the linear

164   elastic range. Measurements were performed with a set-point of 2 µN and a loading rate of

165   500 µN/s. The measured reduced modulus E_r is related to the indenter and sample Young's

166   moduli and Poisson's ratios (E_i, v_i) and (E_s, v_s), respectively, by the relation

167   $1/E_r = \left(1 - v_i^2\right)/E_i + \left(1 - v_s^2\right)/E_s$ which is derived from contact mechanics [37], with $E_i = 1140$

168   GPa and $v_i = 0.07$. In our case, both indenter and substrate were diamond, albeit with

169   different defect densities, so that they contributed to the reduced modulus in approximately

170   equal proportions. In order to obtain a direct comparison between indentation and topography

171   profiles, a SPM map of the region of interest was preliminarily acquired and four indentation

172   measurements were performed at its corners. SEM analysis performed on the tip before and

173   after the indentation revealed that no wear phenomena occurred during the tests. Results are

174   reported in Section 4.2

175

176   **3. Modelling**

177   *3.1. Ab initio simulations*

178   An atomistic approach was employed to simulate the damage-induced modification of

179   the Young's modulus in the material from first principles. For this purpose, the

180   quantum-mechanical *ab initio* code CRYSTAL14 [38, 39] was employed, which allows the

181   prediction of the structural and elastic properties of a defected material [40] through a

182   "supercell" approach [41]. In this context, a supercell is a multiple of the unit cell that

183   contains a vacancy at its body center. The CRYSTAL software creates a bulk system by the

184   repetition of such a defective supercell, so that (contrary to the real physical system) the

185   modeled system under investigation is homogeneous, i.e. defects are periodically distributed

186   in the crystal. Supercells of different sizes allowed to simulate different defect densities. As

187   shown in Fig. 3, single-defect cells with 128, 64, 32, 16 and 8 atoms were simulated,

188   corresponding to vacancy densities of 1.4×10^{21} cm^{-3}, 2.8×10^{21} cm^{-3}, 5.5×10^{21} cm^{-3}, 1.1×10^{22}

189   cm^{-3} and 2.2×10^{22} cm^{-3}. For each supercell, the geometry (both fractional coordinates and cell

190   parameters) was first optimized. Then, the full elastic tensor was generated by deforming the

191   unit cell. Second-order derivatives of the total energy with respect to the strain are evaluated

192   in CRYSTAL as a numerical derivative of an analytical gradient [42, 43]. The Young's

193   modulus was thus derived from the elastic constants tensor. Point symmetry was used at all

194   stages of the calculation to reduce the number of components of the elastic tensor to be

195   considered. For each irreducible strain, a deformation was applied to the system, so that N

196   strained configurations were defined according to a strain step. After a loop of N strained

197   configurations, the energy gradients were fitted with single-value-decomposition routines and

198   the first derivatives were determined numerically. Hartee-Fock (HF) and B3LYP

199   Hamiltonians were adopted [44, 45], both of which have been shown to produce particularly

200   accurate results for this kind of system [44], and the described procedure was adopted for

201   both cases. The neutral vacancy in diamond can occur in three spin states, i.e. $S_z = 0, 1, 2$ [46,

202   47]. The spin state of the defect was however found to have a negligible influence on the

203   elastic properties, so that the reported data only refer to the $S_z = 0$ lowest-energy spin state.

204

205   *3.2. Mesoscale model*

206   The dependence of structural/mechanical properties of damaged diamond have

207   previously been estimated using a phenomenological mesoscale model accounting for

208   damage saturation effects at high fluences, based on a "rule of mixtures" approach [27].

209   According to this model, when accounting for defect recombination in the crystal, the

210   vacancy density ρ_V in the depth direction x can be expressed as:

211

212    $$\rho_V(x) = \alpha \cdot \left(1 - \exp\left[-\frac{F \cdot \lambda(x)}{\alpha} \right] \right) \qquad (1)$$

213

214   where $\lambda(x)$ is the linear vacancy density calculated numerically using the SRIM code, F is the

215   implantation fluence and α is the saturation vacancy density. The latter α parameter can be

216   derived as follows: let us consider an initial mass M and volume V_0 of diamond that after

217 implantation expands to a volume V containing n defects (i.e. vacancies), each assigned the

218 same volume v for sake of simplicity. The vacancy density is therefore $\rho_V = n/V$. By

219 neglecting the mass of the implanted ions, the mass density of the implanted diamond volume

220 V is:

221

222 $$\rho = \frac{M}{V} = \frac{M}{V_0 + nv}$$ (2)

223

224 Since $\rho_d = M/V_0 = 3.52$ cm^{-3} is the mass density of unimplanted diamond, we obtain:

225

226 $$\frac{1}{\rho} = \frac{V_0 + nv}{M} = \frac{1}{\rho_d} + \frac{nv}{M} = \frac{1}{\rho_d} + \frac{nv}{\rho V} = \frac{1}{\rho_d} + \frac{\rho_V v}{\rho}$$ (3)

227

228 By rearranging, we obtain:

229

230 $$\frac{\rho}{\rho_d} = 1 - \rho_V v = 1 - f$$ (4)

231

232 where $f = n \cdot v/V = v \cdot \rho_V$ is the volume fraction of vacancies, which correctly implies that $\rho = \rho_d$

233 for $f = 0$, and $\rho = 0$ for $f = 1$. In fact, in our case an upper bound exists for f due to defect

234 recombination effects [24] corresponding to a vacancy density saturation value $\rho_V = \alpha$. This

235 vacancy density saturation value corresponds to an experimentally determined mass density

236 saturation value of $\rho_{aC} = 2.06$ g cm^{-3} [48]. By rearranging Eq. (4) and estimating v as the

237 inverse of the atomic density of diamond ($\gamma = 1.77 \times 10^{23}$ cm^{-3}), we can derive α as:

238

$$\alpha = \gamma\left(1 - \frac{\rho_{aC}}{\rho_d}\right) \approx 7.3 \cdot 10^{23}\, cm^{-3} \tag{5},$$

240

241 consistently with previous works on 2 MeV H$^+$ implantations [49]. This vacancy density is

242 shown in the inset of Fig. 1. The mass density variation $\rho(x)$ can thus be written as:

243

$$\rho(x) = \rho_d - (\rho_d - \rho_{aC}) \cdot \left(1 - \exp\left[-\frac{F \cdot \lambda(x)}{\alpha}\right]\right) \tag{6}$$

245

246 The Young's modulus dependence from the vacancy density can be derived from Quantized

247 Fracture Mechanics (QFM) [17, 50] for the case of single isolated (non-interacting)

248 vacancies:

249

$$E(x) = E_d \cdot \left(1 - \kappa \frac{\rho(x)}{\rho_d}\right) \tag{7}$$

251

252 where κ is an empirical factor related to defect shape and interaction [17].

253

254   *3.3. Finite Element simulations*

255   Finite Element Model (FEM) simulations were carried out using the Structural

256 Mechanics module of the COMSOL Multiphysics 5.0 package. A 3-D model of the

257 implanted diamond sample was created and constrained expansion of the implanted diamond

258   region due to local density reduction was simulated. The latter was numerically modelled

259   according to elasticity theory by introducing residual strains $\varepsilon_i(x)$ in the three principal

260   directions of the implanted material ($i = 1, 2, 3$):

261

262    $$\varepsilon_i(x) = \sqrt[3]{\frac{\rho_d}{\rho(x)}} - 1 \tag{8}$$

263

264   In this way, in an unconstrained expansion the volume variation would be inversely

265   proportional to the density variation. The diamond sample was considered mechanically

266   isotropic as a first approximation. Material density and Young's modulus spatial variations

267   were accounted for using Eqs. (6) and (7). The same functional form, based on a rule of

268   mixtures approach, was assumed for the variation of the Poisson's ratio:

269

270    $$v(x) = v_d - \left(v_d - v_{aC}\right)\left(1 - \exp\left[-\frac{F \cdot \lambda(x)}{\alpha}\right]\right) \tag{9}$$

271

272   where $v_d = 0.07$ and $v_{aC} = 0.34$ are the Poisson's ratios of pristine diamond and amorphous

273   carbon, respectively [51].

274

275   **4. Results and discussion**

276   *4.1. Raman measurements*

277   Figure 4(a) shows several Raman spectra acquired across the end-of-range depth, the

278   blue plot corresponding to the end-of-range position (~25 µm). In the region characterized by

279   the highest damage density a significant decrease of the first-order Raman line at 1332 cm^{-1} is

280   clearly observed which is associated to increasing structural damage, while no pronounced

281   Raman features at ~1630 cm^{-1} and 1680 cm^{-1} (typically attributed to sp^2 defects [32, 52, 53])

282   can be observed. On the other hand, at frequencies lower than the 1st order transition, a broad

283   band between 1000 cm^{-1} and 1300 cm^{-1} appears at the highest damage densities (blue plot),

284   which is commonly attributed to sp^3 defects and in heavily stressed diamond [53, 54]. As for

285   the features at frequencies above the first order transition, it is worth noting that the Raman

286   peak at ~1370 cm^{-1} closely resembles the D band at ~1350 cm^{-1} commonly associated to

287   tetrahedral amorphous carbon characterized by a high sp^3 content [55], while no G band at

288   ~1580 cm^{-1} is observed in our spectra. More likely, the ~1370 cm^{-1} feature can be related

289   (with a slight frequency shift attributed to the effect of different local stress fields) to a

290   feature observed at ~1390 cm^{-1} in highly stressed diamond regions close to laser-induced

291   graphitized areas, which was attributed to sp^3 carbon allotropes (i.e. Z-carbon and hexagonal

292   diamond) subjected to high mechanical stress [56]. A detailed analysis of the obtained Raman

293   spectra is beyond the scope of this work, but it is nonetheless worth remarking that all of the

294   above-mentioned attributions are compatible with a purely-sp^3 diamond-like phase, thus

295   confirming that even in correspondence with the Bragg peak the damaged diamond structure

296   is not subjected to a graphitization process. The progressive reduction of the first-order

297   Raman transition is accompanied by its broadening and shift to lower frequencies. The latter

298   feature is reported in Fig. 4(b), where the peak frequency is reported. The first-order Raman

299   peak corresponding to the Bragg peak is positioned at ~1321 cm^{-1}. In [32], the redshift of the

300   first-order Raman line in defective diamond has been correlated to vacancy density, estimated

301   by the authors in a simple linear approximation as the product between the linear vacancy

302   density predicted by SRIM and the implantation fluence. If such a correlation is applied to the

303   measured ~1321 cm^{-1} value, an estimated vacancy density at the Bragg peak of ~4.5×10^{21} cm$^-$

304   ^{3} is obtained in the above-mentioned linear approximation. If we consider that the SRIM-

305   predicted linear vacancy density in such region is $\sim$4.5$\times$10^4 cm^{-1}, we can obtain an estimation

306   of the implantation fluence of (4.5$\times$10^{21} cm^{-3}) / (4.5$\times$10^4 cm^{-1}) = 1$\times$10^{17} cm^{-2}, in striking

307   agreement with the corresponding experimental value. Again, these correspondences confirm

308   that the highly damaged regions of the sample can be still considered as a highly defective sp^3

309   diamond phase rather than a graphitized phase.

310

311   *4.2. Nanoindentation results*

312   Firstly, an unimplanted region of the sample was probed with the nano-indenter,

313   yielding a value of E_r = (600 $\pm$ 45) GPa for the reduced Young's modulus, which is

314   compatible with values from the literature [28, 29]. This measured reduced modulus value

315   corresponds to an effective Young's modulus of $\hat{E} = E_s / \left[(1 - 2v_s) \cdot (1 + v_s) \right]$ = (1253 $\pm$ 90)

316   GPa, which can be used to write the relations between principal stresses σ_{ii} and strains ε_{ii} in

317   the generalized form of Hooke's law in 3D [57].

318   For the implanted diamond regions, we exploited the nanometric spatial resolution of

319   the instrument (encoded to a resolution of 500 nm), allowing the investigation of the strongly

320   inhomogeneous damage profile in implanted diamond in correspondence with the end-of-

321   range Bragg peak (i.e. between 3 µm and 4 µm), where the variations in damage density and

322   stiffness are more pronounced. Cross-sectional SPM topography and elastic modulus profiles

323   of the implanted area, acquired from linear scans, are reported in Fig. 5: a $\sim$10% decrease in

324   the value of the reduced modulus is clearly visible in correspondence of the surface swelling

325   peak. The position of the features along the depth direction match with the numerical

326   predictions of SRIM Monte Carlo code (see the inset of Fig. 1).

327

328   *4.3. Density/stiffness variations and surface swelling results*

329   Experimental and numerical results for the relative variation of mass density and

330   Young's modulus as a function of vacancy density are presented in Figs. 6a and 6b,

331   respectively. For the mass density variation in Fig. 6a, the predictions of the model (see Eq.

332   (6)) are compared to the results of *ab initio* HF and B3LYP simulations, showing good

333   agreement and confirming the suitability of a model based on damage saturation effects. The

334   results of *ab initio* simulation of the Young's modulus values were therefore fitted with Eq.

335   (7), allowing the determination of the empirical value $\kappa = 4.46$, which is close to the

336   reference value of $\kappa \approx \pi$ indicated in [17] for carbon nanotubes. The numerical predictions of

337   the Young's modulus variation derived from both the model and the *ab initio* simulations

338   were then compared to experimental nanoindentation measurements, as reported in Fig. 6b.

339   Both predictions are compatible with the experimental data within their uncertainties,

340   although the theoretical predictions tend to systematically under-estimate the reduction in

341   Young's modulus value. This tendency is confirmed by a previous experimental dataset from

342   [26] (also included in Fig. 6b), which also falls below numerical predictions. This systematic

343   underestimation by theoretical models can be reasonably attributed to the fact that in all of

344   the above-mentioned approaches only the effect of induced isolated vacancies is modelled,

345   while the possible effects of more complex defect aggregates are disregarded. Nonetheless,

346   the compatibility between theoretical and experimental results is striking, thus indicating that

347   (at least at the reported damage densities, i.e. below $\sim 10^{22}$ vacancies cm^{-3}) the isolated

348   vacancy defect indeed plays a major role in the modification of the mechanical properties of

349   diamond.

350   Finally, we verified the consistency of the QFM-based model with SPM

351   measurements of the damage-induced surface swelling by feeding its predictions of the local

352   variations of mass density (see Eq. (6) and Fig. 6a) and Young's modulus (see Eq. (7) and

353   Fig. 6b) into the FEM simulation of the deformation of the ion-irradiated diamond region.

354   The results are shown in Fig. 7a: the calculated displacement field in the implanted area and

355   in the surrounding diamond crystal is visualized in colour scale, highlighting the localized

356   deformation that reaches a maximum on the top surface in correspondence with the Bragg

357   peak (see also Figs. 1 and 5). As shown in Fig. 7b, the calculated displacements agree very

358   well with the measured surface swelling, with the exception of the region extending beyond

359   the ion end of range depth at ~25 µm, where the theoretical predictions of the surface

360   swelling overestimate the experimental results. This is possibly due to the isotropic (instead

361   of cubic) symmetry used in FEM simulations for both implanted and unimplanted diamond:

362   such an approximation is more appropriate for the partially amorphized implanted material.

363   The SPM measurements show non-zero surface swelling effects (~22.5 nm) at the leading

364   edge of the implanted region, where the vacancy density is negligible, a feature correctly

365   captured by FEM simulations. Since the Young's modulus variation used in the FEM

366   simulations is derived from QFM calculations with a κ interaction parameter derived from *ab*

367   *initio* simulations, the agreement between FEM-calculated and experimentally measured

368   surface displacements represents a significant confirmation of the consistency of obtained

369   results.

370   FEM simulations based on the predictions of multi-scale modelling of the variation of

371   the structural/mechanical properties in ion-implanted diamond can also provide reliable

372   estimates of locally induced strains and stresses, including in the bulk of the implanted

373   crystal, which is not accessible to direct measurements. This is essential when performing

374   diamond microfabrication, since it was recently shown that diamond amorphization is a

375   strain-driven process [48], i.e. it occurs in regions where a defined strain threshold (~16%) is

376   exceeded. Therefore, such a strain (or equivalently, stress) value must be estimated with the

377   highest accuracy. Here, as an example we report in Fig. 7c the Von Mises stress profiles

378   along the *x* direction (i.e. the direction of the incident ion beam), as calculated at three

379   different positions along the z axis, from the top surface ($z = 0$ µm) to the lower border of the

380   implanted region ($z = -h = -100$ µm). As expected, all stress profiles display a pronounced

381   peak at the end-of-range depth of the ions, where the defect density is largest, reaching values

382   of up to 12 GPa at the sample surface. Moreover, a 3-fold decrease of the end-of-range stress

383   value is observed at a depth of ~100 μm. This evidence provides significant insight into an

384   open issue in the state of the art, i.e. the depth dependence of the amorphization threshold for

385   diamond [23, 32, 33, 58-65]. The general (but so far undemonstrated) understanding is that

386   such a threshold increases at increasing implantation depth due to higher internal pressures

387   that do not allow relaxation to graphitic structures [32]. Here we show quantitatively that in

388   fact the opposite is true, i.e. deeper implants induce smaller stresses (and strains). This is

389   nevertheless consistent with experimental observations, i.e. higher defect densities are

390   required at increasing depths to achieve the same amorphization-inducing strain values. The

391   estimated 3-fold increase in amorphisation threshold for a 100 μm depth is consistent with

392   experimentally observed variations in the literature [23, 32, 33, 58-65].

393

394   **5. Conclusions**

395   A systematic study of the variation of the structural and mechanical properties of

396   defected diamond was carried out with cross-sectional Raman, SPM and nano-indentation

397   measurements carried on MeV-ion-implanted samples. The experimental results display a

398   very satisfactory agreement with complementary *ab initio* atomistic and mesoscale models,

399   also when integrated in FEM simulations. Measurements show that a softening effect of up to

400   15% in diamond, i.e. the hardest known bulk material, can potentially be obtained in a

401   controlled manner using ion irradiation and/or FIB techniques without incurring in the full

402   amorphization/graphitization of the pristine crystal. Simulations predict that this effect can

403   reach nearly 50% for higher damage densities (~ $2.2 \cdot 10^{22}$ cm^{-3}), still lying below the

404   graphitization threshold for diamond ($\sim 2.8 \cdot 10^{22}$ cm^{-3}) [48]. The proposed approach opens the

405   way to the possibility of achieving a three-dimensional control and tuning of the Young's

406   modulus of diamond with a micrometric spatial resolution by adopting advanced

407   microfabrication techniques, e.g. lateral irradiation configurations, multiple implantations,

408   and/or appropriate masking processes. Furthermore, this work demonstrates the possibility of

409   obtaining through FEM simulations an accurate mapping of the stress fields present in the

410   ion-damaged material, allowing for a useful control during various microfabrication stages.

411   Simulations show that deeper implants require a higher density of induced defects to promote

412   amorphization, confirming both the strain-driven mechanism proposed in previous works

413   [48] and the generally observed increase of the graphitization threshold for deeper ion

414   implantations [23, 32, 33, 58-65].

609

610 Fig. 4: a) Micro-Raman spectra acquired across the highly damaged region; the spectra are

611 displaced along the vertical axis for sake of readability; the blue spectrum corresponds to the

612 Bragg peak region at the end of ion range; b) corresponding values of the shift of the first-

613 order Raman peak measured at different positions across the sample depth; the highlighted

614 datapoints correspond to spectra of the same color in a).

615

616 Fig. 5: SPM topography (blue circular dots, scale on the left) and Young's modulus (red

617 square dots, scale on the right) depth profiles of the implanted area acquired along the same

618 linear scan in correspondence with the end-of-range Bragg peak.

619

620 Fig. 6: a) mass density percentage reduction obtained as a function of vacancy density from

621 ab initio (blue diamond and red square dots for HF and B3LYP Hamiltonians, respectively)

622 and mesoscale (continuous black line) simulations; b) Young's modulus percentage reduction

623 as a function of vacancy density obtained in nanoindentation experiments (black triangular

624 dots), from ab initio simulations using HF and B3LYP hamiltonians (blue diamond and red

625 square dots, respectively), from Quantum Fracture Mechanics calculations (continuous black

626 line) and from experimental data in the literature [26] (green circular dots).

627

628 Fig. 7: a) FEM-simulated displacements (in colour scale) in a laterally implanted diamond

629 sample, on an area of height h = 100 µm. b) SPM topography and FEM simulations

630 representing the swelling effect over the whole ion penetration depth (left scale) and SRIM

631 vacancy density profile (right scale). c) Calculated Von Mises stress variation in the y

632 direction at three different depths from the sample surface: z = 0 µm, −50 µm and −100 µm.
