Abstract. The malfunction of safety-critical systems may cause damage to people and the environment. Software within those systems is rigorously designed and verified according to domain specific guidance, such as ISO26262 for automotive safety. This paper describes academic and industrial co-operation in tool development to support one of the most stringent of the requirements — achieving full code coverage in requirements-driven testing.

We present a verification workflow supported by a tool that integrates the coverage measurement tool RapiCover with the test-vector generator FShell. The tool assists closing the coverage gap by providing the engineer with test vectors that help in debugging coverage-related code quality issues and creating new test cases, as well as justifying the presence of unreachable parts of the code in order to finally achieve full effective coverage according to the required criteria.

To illustrate the practical utility of the tool, we report about an application of the tool to a case study from automotive industry.

1 Introduction

Software within safety-critical systems must undergo strict design and verification procedures prior to their deployment. The recently published ISO26262 standard \cite{ISO26262} describes the safety life cycle for electrical, electronic and software components in the automotive domain. Different activities are required at different stages of the life cycle, helping ensure that system safety requirements are met by the implemented design. The rigor to which these are carried out depends on the severity of consequences of failure of the various components. Components with automotive safety integrity level (ASIL) D have the most stringent requirements, and ASIL A the least strict. One of the key required activities for software is to demonstrate the extent to which testing has exercised source code, also known as code coverage. This can be a challenging and expensive task \cite{coverageChallenges}, with much manual input required to achieve adequate coverage results.

This paper presents work undertaken within the Verification and Testing to Support Functional Safety Standards (VeTeSS) project, which is developing new
tools and processes to meet ISO26262. The main contribution of this paper is an integration of the FShell tool [8] with an industrial code coverage tool (Rapi-Cover) in order to generate extra test cases and increase code coverage results. An additional contribution is to present a discussion as to how this technology might be most appropriately used within the safety life cycle. Achieving 100% code coverage can be a complex and difficult task, so tools to assist the process are desirable, however there is a need to ensure that any additional automatically generated tests still address system safety requirements.

Safety standards require different depths of coverage depending on the ASIL of the software. The requirements of ISO26262 are summarized in Tab. 1. The aim of requirements-based software testing is to ensure the different types of coverage are achieved to 100% for each of the categories required. In practice this can be extremely difficult, e.g. defensive coding can be hard to provide test vectors for. Another example is code that may be deactivated in particular modes of operation. Sometimes there is not an obvious cause for lack of coverage after manual review. In this situation, generating test vectors automatically can be beneficial to the user providing faster turnaround and improved coverage results.

This paper is laid out as follows. In Sec. 2 we provide background to the coverage problem being tackled, and criteria for success. In Sec. 3 we describe the specific tool integration. Sec. 4 describes an industrial automotive case study. Sec. 5 looks at both previous work and some of the lessons learned from the implementation experience, and suggested improvements. Finally we present conclusions and further work.

The contribution of this paper is by and large of practical nature: the integration of formal-methods based tools with industrial testing software. In the safety-critical domain these two areas are generally separated from one another, with formal methodology used only for small and critical sections of software to prove correctness and viewed as an expensive procedure. In some cases the methods are seen in direct odds to one another [6]. The tool is at a prototype stage of development, and the authors are working with industrial partners to assess future improvements to prepare its commercialization, as described in Sec. 5.

2 Assisted Coverage Closure

Testing has to satisfy two objectives: it has to be effective, and it has to be cost-effective. Testing is effective if it can distinguish a correct product from one that is incorrect. Testing is cost-effective if it can achieve all it needs to do at the lowest cost (which usually means the fewest tests, least amount of effort and shortest amount of time).

Safety standards like ISO26262 and DO-178B/C demand requirements-driven testing to increase confidence in correct behavior of the software implemented. Correct behavior means that the software implements the behavior specified in the requirements and that it does not implement any unspecified behaviors. As a quality metrics they demand the measurement of coverage according to certain criteria as listed in Tab. 1 for instance. The rationale behind using code coverage as a quality metrics for assessing the achieved requirements coverage of a test suite is the following: Suppose we have a test suite that presumably covers each case in the requirements specification, then, obviously, missing or erroneously implemented features may be observed by failing test cases, whereas the lack of coverage, e.g. according to the MC/DC criterion, indicates that there is behavior in the software which is not exercised by a test case. This may hint at the following software and test quality problems:

(A) Some cases in the requirements specification have been forgotten. These requirements have to be covered by additional test cases.

(B) Features have been implemented that are not needed. Unspecified features are not allowed in safety-critical software and have to be removed.

(C) The requirements specification is too vague or ambiguous to describe a feature completely. The specification must be disambiguated and refined.

(D) Parts of the code are unreachable. The reasons may be:

(1) A programming error that has to be fixed.

(2) Code generated from high-level models often contains unreachable code if the code generator is unable to eliminate infeasible conditionals.

(3) It may actually be intended in case of defensive programming and error handling.

In the latter case, fault injection testing is required to exercise these features [9]. Dependent on the policy regarding unreachable code, case (2) can be handled through justification of non-coverability, tuning the model or the code generator, or post-processing of generated code.

The difficulty for the software developer consists in distinguishing above cases. This is an extremely time consuming and, hence, expensive task that calls for tool assistance.

2.1 Coverage Closure Problem

Given

– an implementation under test (e.g. C code generated from a Simulink model),
– an initial test suite (crafted manually or generated by some other test suite generation techniques), and
– a coverage criterion (e.g. MC/DC), we aim at increasing effective test coverage by automatically
– generating test vectors that help the developer debug the software in order
to distinguish above reasons (A)–(D) for missing coverage;
– in particular, suggesting additional test vectors that help the developer create
test cases to complete requirements coverage in case (A);
– proving infeasibility of non-covered code, thus giving evidence for arguing non-coverability.

Note that safety standards like to DO-178C [13] allow only requirements-driven test-case generation and explicitly forbid to achieve full structural code coverage by blindly applying automated test-vector generation. This can easily lead to confusion if the distinction between test-case generation and test-vector generation is not clearly made. Test-vector generation can be applied blindly to achieve full coverage, but it is without use by itself. A test vector is only a part of a test case because it lacks the element that provides information about the correctness of the software, i.e. the expected test result. Only the requirements can tell the test engineer what the expected test result has to be. Test-case generation is thus always based on the requirements (or a formalized model thereof if available). Our objective is to provide assistance for test-case generation to bridge the coverage gap.

2.2 Coverage Measurement
Combining a test-case generator with a coverage tool provides immediate access to test vectors needed to obtain the level of coverage required for your qualification level.

Coverage tools determine which parts of the code have been executed by using instrumentation. Instrumentation points are automatically inserted at specific points in the code. If an instrumentation point is executed, this is recorded in its execution data. After test completion, the coverage tool analyzes the execution data to determine which parts of the source code have been executed. The tool then computes the level of coverage achieved by the tests.

We use the coverage tool RapiCover, which is part of the RVS tool suite developed by Rapita Systems Ltd.

2.3 Test Vector Generation by Bounded Model Checking
We use the test vector generator, FShell [8] (see Sec. 3.2 for details), which is based on the Software Bounded Model Checker for C programs, CBMC [9].

Viewing a program as a transition system with initial states described by the propositional formula \(Init\), and the transition relation \(Trans\), Bounded Model Checking (BMC) [2] can be used to check the existence of a path \(\pi\) of length \(k\) from \(Init\) to another set of states described by the formula \(\psi\). This check is performed by deciding satisfiability of the following formula using a SAT or SMT solver:

\[
Init(s_0) \land \bigwedge_{0 \leq j < k} Trans(s_j, i_j, s_{j+1}) \land \psi(s_k)
\] (1)
If the solver returns the answer “satisfiable”, it also provides a satisfying assignment to the variables \((s_0, i_0, s_1, i_1, \ldots, s_{k-1}, i_{k-1}, s_k)\). The satisfying assignment represents one possible path \(\pi = \langle s_0, s_1, \ldots, s_k \rangle\) from \(Init\) to \(\psi\) and identifies the corresponding input sequence \(\langle i_0, \ldots, i_{k-1} \rangle\).

Besides being useful for refuting safety properties (where \(\psi\) defines the error states), BMC can be used for generating test vectors (where \(\psi\) defines the test goal to be covered).

The analysis performed by CBMC is bit-exact w.r.t. the machine semantics of the execution target and CBMC provides full bit-exact support for floating point arithmetic. Architecture-specific settings can be configured via command line in FShell and RapiCover supports on-target coverage measurement. We are hence guaranteed that the generated test vectors are going to cover the test goals. In addition, using BMC in a test-vector generator permits generating the shortest test vectors possible to cover a certain test goal or even a whole group of test goals, which helps keeping test suites concise and test execution fast \[14\].

An advantage of using a model checker is also its ability to find test vectors for corner cases (“Under which conditions can this floating point variable take the value NaN?”). Moreover, in our experience, due to the high precision of the analysis, it is even very likely to discover inconsistencies and holes in the requirements specification during test-vector generation.

At last, BMC can give a proof of unreachability of a test goal if loops can be unrolled completely; or otherwise, \(k\)-induction \[15\], a BMC-based technique for unbounded model checking, can be used to attempt a proof.

### 2.4 The Coverage Closure Process

The algorithm that we implement to assist the coverage closure process is shown in Fig. 1. It proceeds as follows:

1. We start with an initial test suite that has been crafted manually or has been generated using other test-case generation techniques like directed random testing. The initial test suite may be empty, but many test goals can be easily covered using test-case generation methods that are cheaper than Bounded Model Checking. It is thus recommended to start with such a base test suite.
2. In the next step, this test suite is run using the coverage measurement tool in order to obtain a list of non-covered test goals. Coverage measurement can be performed on a developer machine to obtain approximate coverage, but final certification data has to be obtained by running the test suite on the actual target platform.

3. The test-vector generator takes the list of non-covered test goals and tries to compute input values to cover them. Ideally, the test-vector generator is parametrized with the architectural parameters of the target platform in order to obtain guarantees that the goals are indeed going to be covered. As our test-vector generator is a Bounded Model Checker, there will be three possible outcomes of an attempt to cover test goals:

   (a) A test goal has been covered. In this case this new test vector is presented to the user who has to turn it into a new test case to be added to the test suite. Note that building the new test case is the only part of the process (bold edge) that is not fully automatic since human judgment is required to identify why the corresponding test goal has not been covered in the first place, i.e. distinguishing reasons (A)–(D) in Sec. 2.

   (b) It is infeasible to cover a test goal. This happens when the test-vector generator comes up with a proof of unreachability of the test goal. As mentioned above, a Bounded Model Checker can provide such proofs if the loops have been unwound completely, for instance. In this case, the corresponding test goal can be annotated in the coverage report as proven infeasible to justify its non-coverability. This increases effective coverage by reducing the number of genuinely coverable test goals.

   (c) The goal has not been covered and we were unable to prove infeasibility of the test goal. With a Bounded Model Checker this can happen if the chosen bound $k$ has been too low. In this case the test goal will remain uncovered and it can be tried to cover it with a higher value for $k$ in the next iteration of the process.

4. Coverage of the enhanced test suite is then measured again to identify test goals that remain uncovered, and the process is repeated. Generated tests typically will cover more test goals than intended. Measuring coverage between generating tests increases cost-effectiveness of the process by eliminating unnecessary test-case generations.

5. If there are no more non-covered test goals we have achieved full coverage and the process terminates.

Note that the process depicted in Fig. 1 is not specific to our tool but applies in general. In particular, it does not rely on the test-vector generator to guarantee that a generated test vector covers the test goal it has been generated for, because the coverage measurement tool will check all generated test cases anyway for increasing the coverage. However, the generation of useless test cases can be avoided by using a tool such as FShell that can provide such guarantees.

Then, in theory, termination of the process achieving full coverage can be guaranteed, because embedded software is finite state. In practice, however, this
depends on the reachability diameter of the system [12] and the capacity of the test-vector generator to cope with the system’s size and complexity.

3 FShell plugin for RVS Implementation

The input to the tool is a C program with an initial test suite. The output of the tool is twofold. The first output is a set of generated test vectors that augment the initial test suite to increase its coverage. The second output is a coverage report detailing the level of coverage achieved by the initial test suite, and the extra coverage added by the generated test cases.

FShell has been integrated into RapiCover as context menu option, shown in Fig. 3. RapiCover can be used to select a single function, call, statement, decision or branch. The tool then uses FShell to generate a test vector for this element. Alternatively, the tool has a button to generate as much coverage as possible. When this option is chosen, the tool goes around the loop described in Fig. 1 using FShell to repeatedly generate test cases to increase the coverage as much as possible, verifying the obtained coverage with RapiCover.

There is tension between the need to demonstrate that the activities prescribed by ISO26262 have been met in spirit as well as with quantifiable criteria. Recall that achieving 100% code coverage during testing does not ensure the code meets its intent. Consequently the FShell plug-in would be provided as advisory service, generating candidate test vectors, which a user can examine to help them identify why their planned testing was inadequate. Values generated need to be assessed for being valid for the system under test, i.e. reflect real world values that could be input to a function, e.g. from a sensor.

---

4 RVS is licensed software. An evaluation version can be requested from [http://www.rapitasystems.com](http://www.rapitasystems.com). The licensing policy disallows anonymous licenses. To compensate for this, we provide a video showing the plug-in here: [https://drive.google.com/file/d/0B7xeLJ8vk3w8Y094TVc4Rmh0S0k](https://drive.google.com/file/d/0B7xeLJ8vk3w8Y094TVc4Rmh0S0k).
3.1 Introduction to RapiCover

RapiCover uses instrumentation to determine which program parts have been executed. Instrumentation points are automatically inserted at specific points in the code. Execution of an instrumentation point is recorded in its execution data. Upon test completion, RapiCover analyzes the execution data to determine which instrumentation points have been hit.

The first step in the RapiCover analysis process is to create an instrumented build of the application (1) in Fig. 2. RapiCover automatically adds instrumentation points (2) in Fig. 2 to the source code.

The instrumentation code itself takes the form of very lightweight measurement code that is written for each target to ensure minimal impact on the performance of the software, and to support on target testing for environments with limited resources. The instrumented software and possibly an instrumentation library are compiled and linked using the standard compiler tool chain. The executable produced is then downloaded onto the target hardware. The executable is exercised and instrumentation data (3) in Fig. 2 is generated and retrieved. This data is used to generate coverage metrics.

3.2 Introduction to FShell

FShell is an extended testing environment for C programs supporting a rich scripting language interface. FShell’s interface is designed as a database engine, dispatching queries about the program to various program analysis tools. These queries are expressed in the FShell Query Language (FQL). Users formulate test

http://www.rapitasystems.com/products/rapicover
Available from: http://forsyte.at/software/fshell
specifications and coverage criteria, challenging FShell to produce test suites and input assignments covering the requested patterns. The program supports a rich and extensive interface. The expressions used for the FShell plugin for RVS implementation are listed in Tab. 2 with syntax and examples.

<table>
<thead>
<tr>
<th>Expression Name</th>
<th>Syntax</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>Function Call</td>

<td>&quot;NOT(...)&quot; &quot;NOT(@CALL(X))&quot;</td>
<td></td>
</tr>
<tr>
<td>Repetition</td>
<td>*</td>
<td>@CALL(X)*</td>
</tr>
<tr>
<td>Alternative</td>
<td>+</td>
<td>(@CALL(X) + @CALL(Y))</td>
</tr>
</tbody>
</table>

Table 2. FShell expressions

@CALL(X) requires generated test cases to call function X. This is the only primitive expression used in the module. The concatenation operator . joins two expressions, requiring them to be satisfied subsequently. As an example, a test case generated by @CALL(X).@CALL(Y) covers a call to X immediately followed by Y. This is similar to the sequence operator ->, which requires the second call to occur eventually. @CALL(X)->@CALL(Y) is thus fulfilled if a call to X is eventually followed by a call to Y. The negation “NOT(@CALL(X))” is satisfied by every statement except a call to function X. The repetition operator is implemented along the lines of its regular expression pendant, such that @CALL(X)* is satisfied by a series of calls to X. Finally, the alternative operator implements logical disjunction, such that (@CALL(X) + @CALL(Y)) will be satisfied if either a call to X or Y occurs.

The expressions and operators above are all that is used by the FShell plugin to generate the test vectors requested by RapiCover. Sec. 3.3 illustrates how these expressions are used to convert test goals to equivalent FQL queries.

3.3 Use of FShell within RapiCover

The FShell plugin for RVS translates test goals requested by RapiCover into FQL queries covering these goals in FShell, as illustrated in Fig. 4. Test goals are specified using marker elements from the RapiCover instrumentation, which can identify arbitrary statements in the source code by assigning them an instrumentation point id. In accordance with MC/DC criteria, decisions and their constituting conditions are further identified using unique decision and condition point ids.

Fig. 4 shows an example program before and after RapiCover instrumentation. The module supports two categories of test goals: Instrumentation Point Path Test Goals and Condition Test Goals. The former specifies a simple series...
of instrumentation points to be covered by FShell. The system also permits inclusive or and negation operators in instrumentation point paths, allowing to specify a choice of instrumentation points to be covered or to make sure that a requested instrumentation point is not covered by the provided test vector. As an example, the instrumentation point path 1->5->6 in Fig. 5 is only covered if the decision in the if statement evaluates to true. Conversely, the path 1->NOT(5)->6 is only covered if it evaluates to false. The former can be achieved with inputs a=1, b=1, c=2, whereas the latter could be covered using the input vector a=1, b=2, c=2. Condition Test Goals on the other hand are specified by a single decision point and multiple condition points, as well as the desired truth value for each decision and condition. This allows us to cover branch conditions with precise values for its sub-conditions. As an example, the condition test goal (4,true) -> (2,false) -> (3,true) would be covered by the input vector a=1, b=2, c=3.

The instrumentation elements introduced by RapiCover need to be mapped to an equivalent FQL query using the features presented in Tab. 2.

| Table 3. Test Goal Types and FShell Queries |
purpose, we replace their default implementation in RapiCover by synthesized substitutions which are optimized for efficient tracking by FShell. These mock implementations are synthesized for each query and injected into the program on-the-fly at analysis time. Standard FQL queries are then enough to examine these augmented models for the specified coverage goals. Tab. 3 shows explicitly how these goals can described using the FShell query syntax.

4 Evaluation

The FShell plugin for RVS has been tested using an industrial automotive use case, for a software managed controller.

4.1 Case Study: e-Shift Park Control Unit

To illustrate the features and utility of the tool, we applied it to the software of an e-Shift Park Control Unit. This system is in charge of the management of the mechanical park lock that blocks or unblocks the transmission to avoid unwanted movement of the vehicle when stopped. The park mode is enabled either by command of the driver via the gear lever (PRND: park/rear/neutral/drive) or automatically.

Fig. 6 shows the architectural elements the e-Park system is communicating with. The vehicle control unit monitors the status of the vehicle via sensors and informs the driver, in particular, about the speed of the vehicle and the status of the gears via the dashboard. The e-Park Control Unit is responsible for taking control decisions when to actuate the mechanical park lock system.

Among many others, the following requirements have to be fulfilled:
1. Parking mode is engaged if vehicle speed is below 6 km/h and the driver presses parking button (P) and brake pedal.
2. If vehicle speed is above 6 km/h and the driver presses the parking button (P) and brake pedal then commands from the accelerator pedal are ignored; parking mode is activated as soon as speed decreases below 6 km/h.
3. If vehicle speed is below 6 km/h and the driver presses the driving button (D) and brake pedal, then forward driving mode is enabled.
4. If vehicle speed is above 6 km/h then backward driving mode (R) is inhibited.

The C code was provided by Centro Ricerche Fiat under a GPL-like license and can be downloaded here: [https://drive.google.com/file/d/0B22MA57MHHBkamhQMmpEQlRWVG8]. The C code was generated from a Simulink model that has not been disclosed, unfortunately.
As is typical for embedded software, the e-Park Control Unit software consists of tasks that — after initialization of the system on start-up — execute periodically in the control loop until system shutdown. A test vector hence consists of a sequence of input values (sensor values and messages received via the communication system) that may change in each control loop iteration. We call the number of iterations the length of the test vector.

To generate valid test vectors, a model of the vehicle is required. Otherwise, the test vector generator may produce results that are known not to occur in the running system, such as infinite vehicle velocity. For the case study this model consisted of assumptions about the input value ranges, such as “The speed of the car will not exceed 1000 km/h, or reduce below 0 km/h.” These assumptions are part of the admissible operating conditions as stated in the requirements specification.

4.2 Experimental Setup

In order to evaluate the FShell plugin for RVS, we used the C source code of the e-Shift case study (approx. 4KLOC) and started out with an initial test suite consisting of 100 random test vectors uniformly distributed over the admissible input ranges. Then we incrementally extended this test suite by additional test vectors generated by the following two approaches:
1. FShell plugin for RVS following the process illustrated in Fig. 1
2. A combination of test vector generation based on random search and greedy test suite reduction.

<table>

</tr>
<tr>
<td>8. If the coverage has increased then keep the test case; otherwise discard it.</td>
<td></td>
</tr>
<tr>
<td>9. Repeat from step 3.</td>
<td></td>
</tr>
</tbody>
</table>

Table 4. Experimental setup of the two approaches that we compare.
We compared the achieved coverage gain and resulting test suite sizes after running both approaches for 8 hours. Tab. 4 describes our experimental setup.

The runtime of FShell is exponential in the loop bound of this main loop. Choosing a too high loop bound results in FShell taking prohibitively long to run, yet setting the loop bound too low results in some branches not being coverable. As mitigation, we started the experiment with a loop bound of 1, then we gradually increased the loop bound to cover those branches that we were not able to cover in previous iterations. As explained in Section 2.1, step 6 in Tab. 4 is not automatic since it needs information from the requirements specification. For the sake of our comparison that does not care about the pass/fail status of the test, we skipped the manual addition of the expected test outcome.

### 4.3 Results

We ran the experiment for 8 hours. The first approach spent more than 99% of this time within FShell. Within this time frame, the loop bound reached 2, and thus not all branches could be covered. Nevertheless an increased coverage was achieved as detailed in Tab. 5 which shows the baseline coverage on the initial test suite (second column from the left) and the increase in percentage of coverage gained by the tool in this experiment (rightmost column). The code under test implements a state machine, which is mostly decisions with very few functions and calls, which is why we focussed on decision and statement coverage for our evaluation.

To underpin the benefit of our tool we compared these results to the second approach described in Tab. 4, a random search test generation strategy. Tab. 5 shows four snapshots of this search (middle columns) after exploring 500, 1000, 5000 and eventually 6092 test vectors of length 5 out of the admissible input range. The results show that more than 99.99% of the generated test vectors
added by the random search are redundant and do not increase the coverage of the suite. This confirms that the system under test represents a particularly challenging case for black-box test case generation and that only very few test vectors in the input range lead to actual coverage increase.

On the other hand, the FShell plugin for RVS achieves a significantly larger increase in the same amount of time in both statement and MC/DC coverage. In addition to this, the plug-in achieves this increased coverage with only half as many new test vectors as the random approach, leading to an overall smaller and more efficient test suite.

This evaluation thus underlines the benefit from our tool integration to support the coverage closure process on an industrial case study. The expected reduction in manual work needs to be investigated in a broader industrial evaluation involving verification engineers performing the entire coverage closure process.

5 Background Context and Applicability

5.1 Novelty of the Approach

There is much work existing for test case generation using Model Checking techniques [5], but a smaller amount targeted directly at the high criticality safety domain where the criterion and frameworks for test case generation are restricted. A useful survey relating to MC/DC can be found in [17]. In [7] Ghani and Clark present a search based approach to generating test frameworks. There are two issues with the approach presented, firstly that it is applied to Java—a language which is rarely used for safety-critical software, and particularly not for the most critical software. The second is more subtle: the test cases were generated to ensure that the minimal set of truth tables for MC/DC were exercised, but without consideration of the validity of any of the test data. Additionally, we emphasize that our approach takes into account existing coverage that has already been achieved and complements the requirements based testing, rather than completely replacing it.

Other work such as [11] looks at modification of the original source through mutation testing in order to assess effectiveness of the tests. This could be considered an adjunct to our methodology, but at present mutation testing is not widely adopted by industry. Jones [10] considers test prioritization and test suite reduction, but not new test case generation.

5.2 Wider Issues and Lessons Learnt

In order to encourage wider adoption of this integrated tool, we need to consider where it would fit in users’ workflow and verification processes, as well as meeting the practical requirements of the standard. As noted earlier, fully automated by only 1.3% while test execution times would double and only half as many test vectors could be explored.
code coverage testing is not desirable as it misses the intent of the requirements based testing process. However, achieving full code coverage is a difficult task, and often requires a large amount of manual inspection of coverage results to examine what was missing. Hence providing the user with suggested test data is potentially very valuable and could improve productivity in one of the most time consuming and expensive parts of the safety certification process.

Another benefit of integrating test case generation and coverage measurement is test suite reduction. The coverage measurement tool returns for each test case a list of covered goals. Test suite reduction is hence the computation of a minimal set cover (an $NP$-complete problem). Approximate algorithms \[16\] may be used to achieve this in reasonable runtimes.

FShell uses a class of semantically exact, but computationally expensive, $NP$-complete algorithms relying on SAT solvers. Depending on the programs or problems posed to the solver the analysis may take long time to complete. Initial feedback on the tool showed that the concept was very well received by Automotive engineers. Speed was considered an issue, however, keeping in mind that today’s practice for full coverage testing may take several person months with an estimated cost of $100 per LOC there is great potential for cutting down time and cost spent in verification by running an automated tool in the background for a couple of days.

Initially, we sometimes failed to validate that a test vector that was generated to cover a test goal actually covers that test goal. E.g., one reason were imprecise number representations in the test vector output. Using the exact hexadecimal representation for floating point constants instead of the imprecise decimal one fixed the problem. This highlights the value of bit-exact analysis as well as the importance of re-validating coverage using RapiCover in the process (Fig. 1).

Note also that this process itself is independent of the tools used which offers a high degree of flexibility. On the one hand, it is planned that in future RVS will support alternative backends in place of FShell. On the other hand, FShell can be combined – without changing the picture in Fig. 1 – with a mutation testing tool (in place of RapiCover) to generate test vectors to improve mutation coverage.

6 Conclusion

This paper has demonstrated the successful integration of the FShell tool with an industrial code coverage tool. Using the integrated tools we were able to increase MC/DC code coverage of an existing, sizeable test suite for an industrial automotive case study from 28.4% to 33.6%. When compared to a random black-box test vector generation strategy, our approach was able to generate a 1.5 times higher coverage increase within the same amount of time. Our tool achieves this coverage gain with half as many test vectors, and these test vectors are much shorter than those generated by random search, leading to more more compact test suites and faster test execution cycles. Moreover, the integration of the two
tools simplifies test case generation and coverage measurement work flows into a unified process.

Future work will consider better integration with the debugging environment to inspect test vectors, and warning the user about potentially unrealistic environment assumptions such as \(\infty\) for vehicle speed. In addition, better support should be provided for exporting the test vectors into the users' existing test suite and testing framework.
