## Abstract

When investing in cyber security resources, information security managers have to follow effective decision-making strategies. We refer to this as the cyber security investment challenge. In this paper, we consider three possible decision support methodologies for security managers to tackle this challenge. We consider methods based on game theory, combinatorial optimisation, and a hybrid of the two. Our modelling starts by building a framework where we can investigate the effectiveness of a cyber security control regarding the protection of different assets seen as targets in presence of commodity threats. As game theory captures the interaction between the endogenous organisation's and attackers' decisions, we consider a 2-person control game between the security manager who has to choose among different implementation levels of a cyber security control, and

<sup>3</sup>Queen Mary University of London.

a commodity attacker who chooses among different targets to attack. The pure game theoretical methodology consists of a large game including all controls and all threats. In the hybrid methodology the game solutions of individual control-games along with their direct costs (e.g. financial) are combined with a knapsack algorithm to derive an optimal investment strategy. The combinatorial optimisation technique consists of a multi-objective multiple choice knapsack based strategy. To compare these approaches we built a decision support tool and a case study regarding current government guidelines. The endeavour of this work is to highlight the weaknesses and strengths of different investment methodologies for cyber security, the benefit of their interaction, and the impact that indirect costs have on cyber security investment. Going a step further in validating our work, we have shown that our decision support tool provides the same advice with the one advocated by the UK government with regard to the requirements for basic technical protection from cyber attacks in SMEs.

*Keywords:* Cyber security investments decision support, Game theory, Optimisation.

## 1. Introduction

One of the biggest issues facing organisations today is how they are able to defend themselves from potential cyber attacks. The range and scope of these unknown attacks create the need for organisations to prioritise the manner in which they defend themselves. With this each organisation needs to consider the threats that they are most at risk from and act in such a way so as to reduce the vulnerability across as many relevant vulnerabilities as possible. This is a particularly difficult task that many Chief Information Security Officers (CISOs) are not confident in achieving while in a report published by Deloitte and NASCIO [1], 75.5% of CISOs cited lack of sufficient budget as a top challenge. It is this perceived lack of sufficient funding that this work wishes to address. As approximately 72% of cyber breaches occur at Small-Medium Enterprises (SMEs) [2], we have decided to investigate cyber security investment

decisions for SMEs. In addition to SMEs being attractive targets for cyber at-  
15 tackers, from our work with local SMEs we have identified that they are heavily  
restricted with the available funding for cyber security, generally working with  
a fixed budget with little to no additional funding being made available for cy-  
ber security purposes. It is generally perceived that this budget is insufficient  
for them to cover all of the vulnerabilities that their system may have. In this  
20 way organisations have to make trade-offs with regard to how they defend their  
systems.

When an organisation is making decisions regarding the defence of their net-  
work, they generally have to consider two critical factors; the cost of implement-  
ing a particular defence and the impact that defence has on the business. The  
25 first of these has been discussed, stating that a company can only implement  
defences that are within their limited budget, considered the *Direct Cost* of the  
defence. However we question whether the apparently most optimal defence,  
based solely on direct costs, is the correct choice for an organisation. The rea-  
son behind this lies with the second criteria, such that the manner in which a  
30 defence is implemented will likely have some effect on either the operation of  
the system or the users of the system. These effects may cause a reduction in  
the speed that tasks can be performed by users or by a weakening of the defence  
caused by users circumventing the controls in order to more easily perform their  
required tasks. We consider that these factors create additional *indirect costs*  
35 for implementing a given defence. These two factors are at the core of our work  
into the *decision support of how to use the limited financial budget available to  
best protect against cyber attacks*.

The approach taken in this work is to model attackers using *commodity cyber  
threats* against SMEs, where the attacker is using commonly available attack  
40 vectors against known defendable vulnerabilities. While this doesn't negate the  
possibility of zero-day vulnerabilities, it removes the expectation that it is in  
the best interest of either player to invest heavily in order to either find a new  
vulnerability or be able to protect against these unknown vulnerabilities. The  
same approach has been taken by the UK government to provide cyber security

45 advice to SMEs [3] and published in a report called “Cyber Essentials Scheme: Requirements for basic technical protection from cyber attacks”.

The seminal work of Anderson [4] considers the traps that defenders may fall into in finding bugs and protecting their systems, where it only needs to be a single unseen vulnerability that exposes the whole of a network. Important  
50 to the modelling is the concept that the defenders have to attempt to *defend everywhere*. This is due to the fact that attackers can strike anywhere they wish. We can highlight this observation by assuming that the defence provided by optimal budget allocations can only be considered as strong as the defence of the *weakest target*, as defined in [5]. This is because the weakest target is at  
55 most risk from an attacker who can potentially attack anywhere. Our approach is quite different to Anderson’s as we focus on developing *cyber security decision support tools* to assist security managers on how to spend a cyber security budget in terms of different controls acquisition and implementation.

In a nutshell, this work proposes a two stage model designed to aid security  
60 managers with decisions regarding the optimal allocation of a cyber security budget. We analyse the two stages of the model by first presenting an overview of the environment from which we define the problem of *cyber security investment*, identifying a unique manner for reasoning about the *targets* that a potential attacker has, and the defences associated with those targets. This is done by  
65 considering the physical location of a data asset, which needs to be protected, as well as the degree to which a particular defence, herein referred to as a *control*, is implemented.

We use the above environment to formulate Control Games, which analyse how well each given control performs at different *degrees of implementation*  
70 (i.e. levels). We compute the Nash Equilibrium condition in Control Games, and we motivate the trade-offs required with the indirect costs. The Nash Equilibrium of a control-game dictates the most efficient manner, in which, a control should be implemented. The solution to each control-game alone is insufficient in dictating the optimal allocation of an organisation’s cyber security budget. So  
75 to identify the best way to allocate a budget, we formalise the problem as

a *multi-objective multiple choice Knapsack problem*. We motivate the use of this methodology by comparing the two-stage model to two alternative methods. Firstly, we model the scenario as an one shot game that aims to optimise the defence including *direct costs*, and secondly a Knapsack problem that considers only pure strategies for each control level including indirect costs. In both cases we highlight where our proposed method is able to outperform alternative methods.

This paper significantly extends the results initially presented in [6]. Its additional contributions include: enriching the mathematical notation to represent more coherent game information; providing a more in-depth mathematical analysis of Control Games' equilibria; comparing the previously proposed, in [6], method of investment, which was based on both Control games and multi-objective Knapsack optimisation, to (i) a pure multi-objective Knapsack optimisation, and (ii) a Full Game approach, where we consider all possible controls, levels, and targets under a single very large game; implementing a large scale case study using real world data from various reputable sources; and drawing thorough insights regarding the effectiveness of our cyber security investment method and highlighting how it is in line with [3].

The remainder of this paper is organised as follows. Section 2 summarises the most important related work at the intersection of cyber security investments and selection of security controls. It also highlights how our approach is different. In Section 3, we introduce the model components, which facilitate the risk assessment prior to selection of security controls and investment. Section 4 uses these components to build a game model and analyse a toy 2x2 game example with a single control with two implementation levels and two targets. This aims to provide a feel for these games and what elements determine the equilibria. In Section 5 we introduce the Control Subgames to support the analysis of large than 2x2 games. In Section 6, we present three different cyber security investment approaches, which we have simulated by using a novel decision support tools developed for the purposes of this paper. In Section 7 we develop a real world case study based on the SANS Critical Security Controls and CWE Top

Software Vulnerabilities. This case study has been used to compare our findings to the set of guidelines that the UK government has published in [3].

## 2. Related Work

110 Our work has been partially inspired by a recent contribution within the field of physical security [7], where the authors address the problem of finding an optimal defensive coverage. The latter is defined as the one maximising the worst-case payoff over the targets in the potential attack set. One of the main ideas of this work we adopt here is that *the more we defend the less rewards the*  
115 *attacker receives.*

As the purpose of cyber security investments methodologies is to lead to the selection of a set of cyber security controls that maximise the benefit of an organisation with respect to some available budget, we find papers that investigate this optimal selection [8, 9, 10, 11, 12] as the most relevant to our work. In this  
120 section, we summarise the most prominent works that investigate allocation of a cyber security budget after conducting cyber security risk assessment. Their differences are briefly also summarised in Table 1.

One of the initial works studying the way to model investment in cyber security is published by Gordon and Loeb [13]. The authors consider the optimum  
125 level of investment given different levels of information security level. The authors propose a model in which for any given vulnerability there are different levels of information security that can be implemented, where a higher level of information security will cause the expected loss to that particular vulnerability to drop. This is modelled as a function of the security level's responsiveness to an  
130 increasing vulnerability in reducing loss. In our model, here, we consider a single value for a vulnerability, and then for each control there are a number of levels of implementation, which represent the information security levels proposed by Gordon and Loeb. The main message of this work is that to maximise the expected benefit from information security investment, an organisation should  
135 spend only a small fraction of the expected loss due to a security breach.

Inspired by [14], Lee et al. apply the profit-at-risk and operational risk modelling approaches to propose a model that facilitates optimal customer information security investments by providing undertaking trade-off analysis between risk and return [15]. The authors define a minimum information security protection level that must be achieved in order investments in a customer privacy  
140 protection to be effective. Rakes et al. [10] extended previous mathematical models [16] to develop an integer programming model that optimises the selection of a subset of security controls to mitigate certain threat level profiles. Authors assessed their model under expected and worst-case threat levels towards deriving  
145 tradeoffs for optimal security planning between these two threat levels. They also demonstrated budget-dependent risk curves giving emphasis in showing how perturbed budget levels affect the aforesaid tradeoffs. In a similar vein, Viduto et al. [11] formulate a multi-objective optimisation problem to select security controls in a cost-effective manner taking into account both financial cost  
150 and security risk. Inspired by [10], Sawik [12] applies two popular in financial engineering (e.g. in portofolio management) measures of risk: value-at-risk and conditional value-at-risk.

In [17], Nagurney et al. propose a supply chain network game theoretic model in which retailers may be subject to a cyberattack and seek to maximise their  
155 expected profits by selecting their optimal product transactions and cybersecurity levels. A successful attack likelihood depends not only on the security level of the retailer per se, but also on that of the other retailers. Authors also show how cyber security investment cost functions vary according to consumers' preferences for the product, which, in turn, depends on both the demand and  
160 the security level. Srinidhi et al. [18] propose an optimisation model to reason about the allocation of cyber security resources to assets that have inherent strength against cyber attack and security-enhancing assets (i.e. security controls). They also investigate the role of cyber insurance in mitigating the effects of breach costs as well as the incentives that both managers and investors in  
165 spending upon cyber security products given that the first (i.e. managers) are more concerned with potential financial losses while the second (i.e. investors)

are reluctant to spend more in strengthening the firm’s security due to spreading their risks by investing in different firms. Lastly, Cavusoglu et al. [19] compare a decision-theoretic approach to game-theoretic approaches for investment in  
170 cyber security. Authors neither use real world data to undertake their risk assessment nor do they investigate the optimal selection of security controls.

### 3. Model Definition

In this section we use game theory to model the interactions between two players; the Defender ( $\mathcal{D}$ ) and the Attacker ( $\mathcal{A}$ ). The Defender might be the  
175 cyber security manager in an SME, and her overall objective is to defend the organisation’s assets from cyber theft, mitigate any potential business disruption, and maintain the organisation’s reputation. On the other hand,  $\mathcal{A}$  is a cyber hacker who tries to subvert the system to her own end, by launching commodity cyber attacks against the organisation  $\mathcal{D}$  is working for. Commod-  
180 ity cyber attacks are based on capabilities and techniques that are available on the internet, where the attack tool can be purchased therefore the adversaries do not develop the attack themselves, and they can only configure the tool for their own use.

In our model,  $\mathcal{D}$  has an available cyber security budget  $B$ , and she wants to  
185 invest in implementing cyber security controls to protect the organisation’s data assets against *commodity attacks*. Each control can be implemented at a different level. Note that the higher the level the greater the degree to which the control

is implemented. After its implementation, each control brings some security benefits to the system, but it is also associated with indirect and direct costs. The challenge  $\mathcal{D}$  has to address is how to decide upon implementation of the different  
190 cyber security controls against *commodity attacks*, given a limited budget  $B$ , and other preferences the organisation has in terms of risks and indirect costs. Our work is based on quantitative risk assessment prior to deciding upon spending a cyber security budget. Alpcan [20] (p. 134) discusses the importance of studying  
195 the quantitative aspects of risk assessment with regard to cyber security in order to better inform decisions makers. In the following we discuss the different components of the model, and we define appropriate terminology and notations, which are consistent throughout this article.

We define the *depth* of a data asset as the location of this asset within the organisation’s structure following the rule: *the higher the depth is, the more confidential data the asset holds*. In other words, a depth determines the importance of the data asset that the organisation loses if a commodity attack (herein referred to as attack) is successful. In this paper, we specify that data assets that are located at the same are depth worth the same value to  $\mathcal{D}$ ’s firm.

We denote the set of cyber security targets within an organisation by  $\mathcal{T} := \{t_i\}$ , the set of vulnerabilities threatened by commodity attacks by  $\mathcal{V} := \{v_z\}$ , and the set of depths by  $\mathcal{D} := \{d_x\}$ . A *cyber security target* is defined as a (*vulnerability, depth*) pair; formally  $t_i := (v_z, d_x)$ . This abstracts any data asset, located at  $d_x$ , that an attack threatens to compromise by exploiting  $v_z$ . We  
205 specify that data assets located at the same depth and having the same vulnerabilities are abstracted by the same target. Each target is associated with an impact value which expresses the level of damage incurred to  $\mathcal{D}$ ’s organisation when  $\mathcal{A}$  succeeds in their attack against that target. The different impact factors can be *data loss*, *business disruption*, and *reputation damage*. Each impact  
210 factor depends on the depth  $d_x$  that the attack targets. Furthermore, there is a *threat value* for each target. This can account, for instance, for the frequency of attacks launched against that target. Each software weakness (we use the terms weakness and vulnerability interchangeably) has some factors that can

determine an overall score. Let  $I: \mathcal{T} \rightarrow \mathbb{Z}^+$  be the random variable which takes  
 220 targets  $t_i$  to the impact value that the compromise of  $t_i$  will have to the organ-  
 isation, and let  $T: \mathcal{T} \rightarrow \mathbb{Z}^+$ , be the random variable which takes target  $t_i \in \mathcal{T}$   
 to its threat value. Aligned with the definition of target,  $I(t_i)$  depends on the  
 depth  $d_x$ , and  $T(t_i)$  depends on the vulnerability  $v_z$ .

A *cyber security control* is the defensive mechanism that  $\mathcal{D}$  can put in place  
 225 to alleviate the risk from one or more attacks by reducing the probability of these  
 attacks successfully exploiting vulnerabilities.  $\mathcal{D}$  chooses to implement a control  
 at a certain level for their organisation. We define the set of implementation  
 levels of a control as  $\mathcal{L} := \{l_\lambda\}$ . The higher the level the greater the degree to  
 which the control is implemented<sup>4</sup>. An implementation level  $l$  has a *degree of*  
 230 *vulnerability mitigation* on each target. This is determined by the efficacy, in  
 terms of cyber defence, of  $l$  on this target. For a pair  $(l, t)$ , which represents the  
 level of implementation of a particular control, we define the random variable  
 $E: \mathcal{L} \times \mathcal{T} \rightarrow [0, 1)$ , which takes a pair of  $(l, t)$  to the efficacy value of  $l$  on  
 $t$ . Here, we have postulated that  $E(l, t) \neq 1$  due to the existence of 0-day  
 235 vulnerabilities that  $\mathcal{A}$  has the potential to exploit. Assume  $\mathcal{D}$  implements a  
 control at  $l$  that has efficacy  $E(l, t)$  on  $t$ . We define the *cyber security loss*  
 random variable  $S(l, t) = I(t)T(t)[1 - E(l, t)]$ . This is the expected damage  
 (e.g. losing some data asset) that  $\mathcal{D}$  suffers when  $t$  is attacked and a control  
 has implemented at level  $l$ . This definition of loss is in line with the well-known  
 240 formula, risk = expected damage ( $I(t)$ )  $\times$  probability of occurrence ( $T(t)$ ) [21].

While the implementation of a cyber security control strengthens the defence  
 of  $\mathcal{D}$ 's organisation, it is associated with two types of costs namely; *indirect* and  
*direct*. Examples of indirect cost are System Performance Cost, Morale Cost,  
 and Re-Training Cost. For a level  $l$  we express its indirect cost by the random  
 245 variable  $C: \mathcal{L} \rightarrow \mathbb{Z}^+$ . From the above we can derive the overall loss of  $\mathcal{D}$ 's  
 organisation. This is equivalent to the sum of the security damages inflicted by  
 $\mathcal{A}$  and the indirect cost for implementing a control at a certain level. Formally,

---

<sup>4</sup>Note that we abuse notation by setting  $l_\lambda = l, t_i = t, v_z = v$ , and  $d_x = d$ .

when  $\mathcal{D}$  implements a control at some level  $i$  then the expected loss of their organisation is derived by  $\sum_t S(l, t) - C(l)$ . The implementation of a control, at some level, has a direct cost, which refers to the budget the organisation must spend to this implementation. For instance, we can split such direct cost into two categories, the Capital Cost and Labour Cost. We express the direct cost of an implementation level  $l$  by the random variable  $\Gamma: \mathcal{L} \rightarrow \mathbb{Z}^+$  that takes implementation levels to the monetary cost of the control implementation.

#### 4. Cyber Security Control Games

In this article we formulate two-player non-cooperative static games, called *Control Games*. The players in a Control Game are the Defender ( $\mathcal{D}$ ), which represents any cyber security decision-maker, and  $\mathcal{A}$ , which represents any cyber hacker who uses commodity attacks. The former defends their organisation's data assets by minimising expected cyber security losses with respect to some indirect costs, while  $\mathcal{A}$  aims at benefiting from compromising these assets.  $\mathcal{D}$  is choosing how to implement a cyber security control (i.e. at which level) and  $\mathcal{A}$  decides which target to attack to exploit its vulnerability at a certain depth. Since we consider a simultaneous game,  $\mathcal{A}$  does not know the control implementation strategy and  $\mathcal{D}$  does not know the attack strategy. We refer to our games as *Control Games* because the basis of our formulation is that  $\mathcal{D}$  has one control at her disposal.

First, we formulate zero-sum Control Games. These represent scenarios where  $\mathcal{A}$  aims at causing the maximum possible damage to  $\mathcal{D}$ . We believe that if we consider a non-zero sum game then a specific threat model must be defined as well. Such a model could consider, for instance, some cost for  $\mathcal{A}$  when undertaking an attack. However cost in terms of cyber attacks is tightly coupled with the adversary's profile. A consideration of a specific threat model would also have some influence on the way  $\mathcal{A}$  sees the different targets as she is after specific goals based on her motivation (i.e. cyber crime, hacktivism, cyber espionage). In this case, different  $\mathcal{A}$  profiles could have been investigated. In

our work here, we have not investigated such profiles and our work is limited to a generic assumption that  $\mathcal{A}$  is taking advantage of commodity attacks that she can purchase from online sources. In other word, we have assumed a set of  
280 attack methods that  $\mathcal{A}$  can choose from but we have not postulated anything about their motivations.

For a given cyber security control,  $\mathcal{D}$  can choose to implement the control at level  $l \in \mathcal{L}$  and therefore her pure strategy set coincides with  $\mathcal{L}$ .  $\mathcal{A}$  selects a vulnerability to exploit at a certain depth. Formally,  $\mathcal{A}$  chooses  $t = \langle v, d \rangle \in \mathcal{T}$ . Thus  
285 the pure strategy set of  $\mathcal{A}$  coincides with  $\mathcal{T}$ . Given that the pure strategy sets of the players are  $\mathcal{L}$  and  $\mathcal{T}$  then  $\mathcal{D}$  has  $m$  pure strategies and  $\mathcal{A}$  has  $n$ , correspondingly. We denote by  $G := \langle \mathbf{A}, \mathbf{E} \rangle$  an  $m \times n$  bi-matrix cyber security game where  $\mathcal{D}$  (i.e. row player) has a payoff matrix  $\mathbf{A} \in \mathbb{R}^{m \times n}$  and the payoff matrix of  $\mathcal{A}$  (i.e. the column player) is denoted by  $\mathbf{E} \in \mathbb{R}^{m \times n}$ .  $\mathcal{D}$  chooses as one of her  
290 pure strategies one of the rows of the payoff bi-matrix  $\langle \mathbf{A}, \mathbf{E} \rangle := [(a_{lt}, e_{lt})]_{l,t}$ . For any pair of strategies  $(l, t)$ ,  $\mathcal{D}$  and  $\mathcal{A}$  have payoff values equivalent to  $a_{lt}$  and  $e_{lt}$ , given by  $a_{lt} := S(l, t) - C(l)$  and  $e_{lt} := -S(l, t) + C(l)$ . Table 2 is the game matrix presenting player's payoffs for the different pure strategy profiles.

A player's mixed strategy is a distribution over the set of their pure strategies. The representation of  $\mathcal{D}$ 's mixed strategy space is a finite probability distribution over the set of the different control implementation levels  $\{l_1, \dots, l_m\}$ . For  
295  $\mathcal{A}$ , the representation of their mixed strategy space is a probability distribution over the different targets  $\{t_1, \dots, t_n\}$ . In this paper we are interested in how different control implementation levels are combined in a proportional manner to give an implementation plan for this control. We call this a *cyber security*  
300 *plan*. This allows us to examine advanced ways of mitigating vulnerabilities.

We occasionally refer to the implementation of a control at a certain level as a *cyber security process*. We can then define the *cyber security plan* as the probability distribution over different cyber security processes. When investing  
305 in cyber security we will be looking into the direct cost of each cyber security plan which is derived as a combination of the different costs of the cyber security processes that comprise this plan.

Table 2: Game matrix.

	$t$	$t'$
$l$	$S(l, t) - C(l), -S(l, t) + C(l)$	$S(l, t') - C(l), -S(l, t') + C(l)$
$l'$	$S(l', t) - C(l'), -S(l', t) + C(l')$	$S(l', t') - C(l'), -S(l', t') + C(l')$

We define  $\mathcal{D}$ 's mixed strategy as the probability distribution  $\Phi = [\phi_1, \dots, \phi_m]$ . This expresses a cyber security plan, where  $\phi_\lambda$  is the probability of implementing the control at  $l_\lambda$ . A cyber security plan can be realised as advice to  $\mathcal{D}$  on how to implement a cyber security control by combining different implementation levels. Although this assumption complicates our analysis at the same time it allows us to reason about equilibria of the control game therefore providing a more effective strategy for  $\mathcal{D}$ . We claim that our model is flexible thus allowing  $\mathcal{D}$  to interpret mixed strategies in different ways to satisfy their requirements. A mixed strategy of  $\mathcal{A}$  is a probability distribution over the different targets and it is denoted by  $\Theta = [\theta_1, \dots, \theta_n]$ , where  $\theta_i$  is the probability of the adversary attacking  $t_i$ . When both players choose a pure strategy randomly according to the probability distributions determined by  $\Phi$  and  $\Theta$ , the expected payoffs to  $\mathcal{D}$  and  $\mathcal{A}$  are  $J_D(\Phi, \Theta) := \sum_{i=1}^n \sum_{\lambda=1}^m \phi_\lambda a_{i\lambda} \theta_i$ , and  $J_A(\Phi, \Theta) := \sum_{i=1}^n \sum_{\lambda=1}^m \phi_\lambda e_{i\lambda} \theta_i$ .

For the remainder of this section, we analyse a specific Control Game. We assume that for a specific target  $t$ ,  $\mathcal{D}$  has only two possible levels at her disposal namely  $l$ , and  $l'$  (e.g. performing penetration testing rarely during a year or often), to implement a control. We define  $\Delta S(t) := S(l', t) - S(l, t)$  and  $\Delta C := C(l') - C(l)$ .  $\Delta S(t)$  is the reduction in damage when  $l'$  is chosen, and  $\Delta C$  is the extra indirect cost of  $l'$  over  $l$ .

**Lemma 1.** *When the reduction in damage achieved by  $l'$  over  $l$  is higher than the extra indirect cost that  $l'$  introduces,  $\mathcal{D}$  chooses  $l'$ .*

PROOF. If the reduction in damage achieved by  $l'$  over  $l$  is higher than the extra indirect cost that  $l'$  then  $\Delta S(t) > \Delta C$ . This can be broken down as,  $S(l', t) - S(l, t) > C(l') - C(l) \Leftrightarrow S(l', t) - C(l') > S(l, t) - C(l) \Leftrightarrow a_{l't} > a_{lt}$ . Therefore, the  $\mathcal{D}$  is incentivised to pick  $l'$  as it has a higher utility.  $\square$

**Lemma 2.** *If  $S(l, t) > S(l, t')$  then Attacker attacks target  $t$ .*

PROOF. For a specific control implementation  $l$  and two targets  $t, t'$ ,  $\mathcal{A}$ 's best  
 335 response can be found by comparing  $e_{lt}, e_{lt'}$ . If  $e_{lt} > e_{lt'} \Leftrightarrow S(l, t) - C(l) >$   
 $S(l, t') - C(l) \Leftrightarrow S(l, t) > S(l, t')$ ,  $\mathcal{A}$  prefers to attack target  $t$ . Specifically we  
 define this property as  $\Delta S(l) := S(l, t') - S(l, t)$ . Therefore, if  $S(l, t) > S(l, t') \Leftrightarrow$   
 $S(l, t') - S(l, t) < 0 \Leftrightarrow \Delta S(l) < 0$ ,  $\mathcal{A}$  chooses  $t$ .  $\square$

Since we are investigating a two-person zero-sum game with finite number of  
 340 actions for both players, and according to Nash [22] it admits at least a Nash  
 Equilibrium (NE) in mixed strategies. Saddle-points correspond to Nash equilibria  
 as discussed in [20]. The following result, from [23], establishes the existence  
 of a saddle (equilibrium) solution in the games we examine and summarises  
 their properties.

345 The investigated cyber security game admits a saddle point in mixed strategies,  
 $(\Phi^*, \Theta^*)$ , with the properties  $\Phi^* = \arg \max_{\Phi} \min_{\Theta} J_U(\Phi, \Theta)$ , and  $\Theta^* =$   
 $\arg \max_{\Theta} \min_{\Phi} J_A(\Phi, \Theta)$ .

**Corollary 3.** *Regardless of the Attacker's strategy, the Nash Defender guarantees a minimum performance, that is an upper limit of expected damage.*

350 PROOF. The minimax theorem states that for zero sum games NE, maxmin  
 and minimax solutions coincide. Therefore  $\Phi^* = \arg \min_{\Phi} \max_{\Theta} J_A(\Phi, \Theta)$ .  $\square$

Since in this work we consider zero sum games, two criticisms are possible:

**Remark 1.** The gain of the Attacker is not, in general, equal to the loss of the defender.

355 **Remark 2.** The Attacker's payoff is not related to the defender indirect costs.  
 We address both Remarks by noticing that a significant class of *realistic cyber security games*  
 can be mathematically reduced to zero sums games. Remark 1 is addressed by the following lemma.

**Lemma 4.** *The equilibrium  $(\Phi^*, \Theta^*)$  in our zero sum cyber security game  $G$   
 360 remains the same in the negative affine transformation of this game in which the Attacker's gain does not equal the Defender's loss.*

PROOF. We claim that a model of the  $\mathcal{A}$  where his payoffs are a negative affine transformation of the  $\mathcal{D}$  loss is a reasonable model. For example by selling stolen data on the black market for only one tenth of the data's value.

365 A negative affine transformation of the Defender's  $\mathbb{A}$  matrix is defined as  $\omega \mathbb{A} + \psi$ , where  $\omega$  is a negative scalar, and  $\psi$  is a constant matrix of the same dimension as  $\mathbb{A}$ . Therefore, in addition to the cyber security game  $G = (\mathbb{A}, -\mathbb{A})$ , we intuitively define the negative affinity of this game as  $G^- = (\mathbb{A}, \omega \mathbb{A} + \psi)$ .

370 Suppose  $\Phi^*, \Theta^*$  are the equilibrium strategies in  $G$ . First, it is easy to see that  $\Phi^*$  is the Defender's equilibrium strategy in both  $G$  and  $G^-$  due to the Defender's game matrix remaining the same. Formally,  $\Phi \mathbb{A} \Theta^* \leq \Phi^* \mathbb{A} \Theta^*$ . Similarly, we prove that  $\Theta^*$  is Attacker's equilibrium strategy in both games. We have that  $\Phi^* (-\mathbb{A}) \Theta \leq \Phi^* (-\mathbb{A}) \Theta^* \Rightarrow \Phi^* \mathbb{A} \Theta \geq \Phi^* \mathbb{A} \Theta^* \Rightarrow \Phi^* (\omega \mathbb{A} + \psi) \Theta \leq \Phi^* (\omega \mathbb{A} + \psi) \Theta^*$ . This means that equilibria are the same in both  $G, G^-$ .  $\square$

375 **Lemma 5.** *A game  $\widehat{G}$  where the Defender's indirect cost  $C$  is a positive affine transformation of the direct cost  $S$ , has the same maxmin solution with  $G$ .*

PROOF. According to the Lemma we have that in  $\widehat{G}$   $\mathcal{D}$ 's payoff is given by  $S - (\kappa S - \mu) = S(1 - \kappa) - \mu$ , where  $\kappa, \mu$  are positive scalars. Assume that at the equilibrium of  $\widehat{G}$   $\mathcal{D}$ 's best response is  $\Phi^*$ . Then we have  $\Phi \left[ S(1 - \kappa) - \mu \right] \Theta^* \leq \Phi^* \left[ S(1 - \kappa) - \mu \right] \Theta^* \Rightarrow \Phi (S - \kappa S - \mu) \Theta^* \leq \Phi^* (S - \kappa S - \mu) \Theta^* \Rightarrow$   
380  $\Phi (S - \mu) \Theta^* \leq \Phi^* (S - \mu) \Theta^* \xrightarrow{\mu=C} \Phi (S - C) \Theta^* \leq \Phi^* (S - C) \Theta^* \Rightarrow \Phi \mathbb{A} \Theta^* \leq \Phi^* \mathbb{A} \Theta^*$ . Therefore  $G, \widehat{G}$  have the same equilibria, and from Corollary 3 these are also maxmin solutions.  $\square$

To illustrate the game approach let's consider a toy example consisting of  
385 a 2-level, and 2-target control games, where  $\mathcal{D}$  and  $\mathcal{A}$  make their decisions simultaneously, or, equivalently, independently of each other. The information sets associated with the the control game, investigated in this section, depicted in Fig. 1; a dashed curve encircling the  $\mathcal{A}$  nodes has been drawn. This indicates that  $\mathcal{A}$  cannot distinguish between these two points. In other words,  $\mathcal{A}$  has to  
390 arrive at a decision without knowing what  $\mathcal{D}$  has actually chosen.

Figure 1: Game tree for the control game with 2 implementation levels and two targets.

Due to the game being zero-sum, we have kept only the payoffs of  $\mathcal{D}$  at the game tree. We also defined the mixed strategy of  $\mathcal{D}$  as the probability distribution  $[\phi, 1 - \phi]$ , where  $\phi$  is the probability of implementing the control at level  $l$ .  $\mathcal{A}$ 's mixed strategy is denoted by  $[\theta, 1 - \theta]$ , where  $\mathcal{A}$  chooses to attack  $t$  with probability  $\theta$ . Table 3 summarizes all possible best responses of the control game for the different conditions discussed in this section.

In a two target, two level control sub-game, it is possible to define the probabilities that each player plays a particular mixed strategy.

**Lemma 6.** *The Nash equilibrium for a control sub-game for the  $\mathcal{D}$ 's, given by  $\phi^* \in [0, 1]$  is  $\phi^* = \frac{\Delta S(l')}{\Delta S(l') - \Delta S(l)}$ .*

PROOF. The  $\mathcal{D}$  wants to make the  $\mathcal{A}$  indifferent to which target they should attack. This is given by equalising the expected payoff of the  $\mathcal{A}$ , thus  $A(t) = \phi^* e_{lt} + (1 - \phi^*) e_{l't}$  and  $A(t') = \phi^* e_{lt'} + (1 - \phi^*) e_{l't'}$ , giving

Table 3: Nash equilibria for the different conditions.

	$\Delta S(t') > \Delta C$		$\Delta S(t') < \Delta C$	
$\Delta S(t) > \Delta C$	$\Delta S(l') > 0$	$(l', t)$	$\Delta S(l') < 0$	$(\phi l', (1 - \theta)t)$
	$\Delta S(l') < 0$	$(l', t')$	$\Delta S(l) > 0$	$((1 - \phi)l, \theta t')$
$\Delta S(t) < \Delta C$	$\Delta S(l) < 0$	$((1 - \phi)l', (1 - \theta)t')$	$\Delta S(l) > 0$	$(l, t)$
	$\Delta S(l') > 0$	$(\phi l, \theta t)$	$\Delta S(l) < 0$	$(l, t')$

$$\phi^* e_{lt} + (1 - \phi^*) e_{l't} = \phi^* e_{lt'} + (1 - \phi^*) e_{l't'}. \quad (1)$$

We can substitute terms such that Eq. (1) can be written in terms of  $e_{lt}$ , hence  
405  $e_{l't} = e_{lt} - \Delta S(t) + \Delta C$ ,  $e_{lt'} = e_{lt} - \Delta S(l)$ , and  $e_{l't'} = e_{lt} - \Delta S(t) + \Delta C - \Delta S(l')$ . By substituting the above equations into Eq. (1) we get  $\phi^* e_{lt} + (1 - \phi^*) (e_{lt} - \Delta S(t) + \Delta C) = \phi^* (e_{lt} - \Delta S(l)) + (1 - \phi^*) (e_{lt} - \Delta S(t) + \Delta C - \Delta S(l')) \Rightarrow \Delta S(l') = \phi^* (\Delta S(l') - \Delta S(l)) \Rightarrow \phi^* = \frac{\Delta S(l')}{\Delta S(l') - \Delta S(l)}$ .  $\square$

**Lemma 7.** *The Nash strategy of the  $\mathcal{A}$  in a control sub-game, is given by  $\theta^* =$   
410  $\frac{\Delta S(t) - \Delta C + \Delta S(l') - \Delta S(l)}{\Delta S(l') - \Delta S(l)}$ .*

PROOF. At the equilibrium, the  $\mathcal{A}$  wants to make the  $\mathcal{D}$  indifferent to which target they should attack. By equalising the expected payoff of the  $\mathcal{D}$  we have that  $D(l) = \theta^* a_{lt} + (1 - \theta^*) a_{l't}$  must equal  $D(l') = \theta^* a_{l't} + (1 - \theta^*) a_{l't'}$ . Therefore  $\theta^* a_{lt} + (1 - \theta^*) a_{l't} = \theta^* a_{l't} + (1 - \theta^*) a_{l't'}$ . We can substitute terms  
415 such that the above equation can be written in terms of  $a_{lt}$ ,  $a_{l't} = a_{lt} + \Delta S(t) - \Delta C$ ,  $a_{l't'} = a_{lt} + \Delta S(l)$ , and  $a_{l't} = a_{lt} + \Delta S(t) - \Delta C + \Delta S(l')$ , and by substituting these equations into the former we get  $\theta^* a_{lt} + (1 - \theta^*) (a_{lt} + \Delta S(l)) = \theta^* (a_{lt} + \Delta S(t) - \Delta C) + (1 - \theta^*) (a_{lt} + \Delta S(t) - \Delta C + \Delta S(l')) \Rightarrow a_{lt} + \Delta S(l) - \theta^* \Delta S(l) = a_{lt} + \Delta S(t) - \Delta C + \Delta S(l') - \theta^* \Delta S(l') \Rightarrow \theta^* = \frac{\Delta S(t) - \Delta C + \Delta S(l') - \Delta S(l)}{\Delta S(l') - \Delta S(l)}$ .  $\square$

## 420 5. Cyber Security Control Subgames

When looking into investing in cyber security one might face the challenge of not having a necessary financial budget to implement the equilibria of a cyber security Control Game. To tackle this challenge we define cyber security Control Subgames, which constitute a Control Game by gradually increasing the  
425 available implementation levels of the control. In this way, we can derive a number of equilibria that can satisfy a wider range of financial capacity. A Control Subgame  $\mathcal{G}_{j\lambda}$  is a game where (i)  $\mathcal{D}$ 's pure strategies correspond to consecutive implementation levels of the control  $j$  starting always from 0 (i.e. fictitious control-game) and including all levels up to  $\lambda$  and, (ii)  $\mathcal{A}$ 's pure strategies are  
430 the different targets akin to pairs of vulnerabilities and depths.

We represent  $\mathcal{D}$ 's mixed strategy, in  $\mathcal{G}_{j\lambda}$ , as the probability distribution  $Q_{j\lambda} = [q_{j0}, \dots, q_{j\lambda}]$ . This expresses a *cybersecurity plan*, where  $q_{jl}$  is the probability of implementing  $c_j$  at level  $l$  in  $\mathcal{G}_{j\lambda}$ . A mixed strategy of  $\mathcal{A}$  is defined as a probability distribution over the different targets, in  $\mathcal{G}_{j\lambda}$ , and it is denoted  
 435 by  $H_{j\lambda} = [h_{j1}, \dots, h_{jn}]$ , where  $h_{ji}$  is the probability of the adversary attacking  $t_i$  when  $\mathcal{D}$  has only  $c_j$  in their possession.  $\mathcal{D}$ 's aim in a Control Subgame is to choose the *Nash cybersecurity plan*  $Q_{j\lambda}^* = [q_{j0}^*, \dots, q_{j\lambda}^*]$ . This consists of  $\lambda$  cybersecurity processes chosen probabilistically as determined by the NE of  $\mathcal{G}_{j\lambda}$ .

To illustrate this we take for example a security control entitled *Vulnerability*  
 440 *Scanning and Automated Patching*, and we assume 5 different implementation levels i.e.  $\{0, 1, 2, 3, 4\}$  where level 4 corresponds to *real-time scanning* while level 2 to *regular scanning*. We say that a mixed strategy  $[0, 0, 0.7, 0, 0.3]$  determines a cyber security plan that dictates the following:  $0.3 \mapsto$  real-time scanning for the 30% of the most important devices;  $0.7 \mapsto$  regular scanning for the remaining  
 445 70% of devices. This mixed strategy can be realised more as an advice to a security manager on how to undertake different control implementations rather than a rigorous set of instructions related only to a time factor. We claim that our model is flexible thus allowing the defender to interpret mixed strategies in different ways to satisfy their requirements.

## 450 6. Cyber Security Investment

The analysis performed in Section 4 has considered a single-control, two-targets, two-levels game. When having  $c$  cyber security controls, our plan for cyber investment is to solve  $c$  Control Games by splitting each of them up to a set of  $m - 1$  Control Subgames with  $n$  targets and up to  $\lambda$  implementation levels  
 455 for each control, where  $\lambda \in \{1, m\}$ . For a Control Game the Control Subgame equilibria constitute the Control Game solution.

Given the Control Subgame equilibria we then use a Knapsack algorithm to provide the general investment solution. The equilibria provide us with information regarding the way in which each security control is *best implemented*, so as

460 to maximise the benefit of the control with regard to both the  $\mathcal{A}$ 's strategy, and  
the indirect costs of the organisation.

It is easy to see that, Control Subgames (and consequently Control Games)  
look only at vulnerabilities that are directly relevant to the control being imple-  
mented. The cyber security investment problem expands to represent all of an  
465 organisation's vulnerabilities and select the best cyber security controls based  
on the outcomes of the Control Games. With regard to an implementation of  
cyber security processes based on the Control Subgame solutions, it is impor-  
tant to understand what a Control Game solution represents in the process of  
making those decisions. In particular this is about what a mixed strategy means  
470 in terms of control implementation.

We motivate the concept of a mixed strategy as a method for trying to define  
where in the system it is most effective to implement the control. Based on our  
interpretation of the structure of a network, this will generally involve protecting  
devices at the highest depth with the strictest controls where possible, then  
475 assigning lower levels of controls to devices and users that operate at depths  
with less sensitive data. This is performed by creating a logical ordering of the  
most important devices, based on the perceived risk of the device or the user, as  
part of a risk assessment methodology. While there may be a logical ordering  
across an organisation for all controls, it often might make more sense to order  
480 users and devices specifically for each control based on vulnerability.

### *6.1. Full Game Representation*

A Full Game representation considers the method of solving the investment  
problem by creating a strategic game containing the set of feasible choices avail-  
able to both players.  $\mathcal{D}$ 's pure strategies are comprised of an implementation  
485 level for each of the controls, and  $\mathcal{A}$ 's pure strategies consist of each target in  
the set of all possible targets. One of the considerations that needs to be made  
is with regards to the budget. A pure game-theoretic solution for the cyber  
investment problem would require modelling  $n$  targets,  $m$  control levels and  $c$   
controls. A naive choice would be to consider  $c \times m \times n$  games. However it is

490 not clear how to force these game solutions to satisfy budget constraints.

A game model satisfying budget constraints could be built using the idea of “schedules” [24], i.e. a pure strategy is a tuple of  $c \times m$  bits where each bit represents the implementation of a control at a particular level, and 1 stands for “implemented” and 0 for “not implemented”. The budget requirement can  
495 be easily imposed on such tuples, for example by only considering tuples whose costs do not exceed the budget. The problem with this is that, in principle, there could be an exponential number of pure strategies, in the order of  $2^{(c \times m)}$ . Also it would be non-trivial to choose appropriate payoffs for such tuples. In this case, we restrict the combination of controls in the payoff matrix to only those  
500 that can be purchased based on the maximum amount of budget.

## 6.2. Hybrid Method

The Hybrid method avoids the problems of the Full Game method by considering the particular game solutions of each Control Game (and consequently the game solutions of all Control Subgames that comprise this Control Game)  
505 as part of an overall combinatorial optimisation problem which we will solve using 0-1 Multiple Choice, Multi-Objective Knapsack. The choice of this type of Knapsack is motivated as follows: “0-1” because each level of implementation of a control is implemented or not implemented; “Multiple Choice” because only one solution for each control (the optimal one) ought to be chosen; and  
510 “Multi-Objective” because each target represents an optimisation objective.

For convenience, we denote the Control Subgame solution by the maximum level of implementation available. For instance, for  $c_j$  and the solution of Control Subgame  $\mathcal{G}_{j\lambda}$  is denoted by  $Q_{j\lambda}^*$ . Let us assume that for control  $j$  the equilibria of all Control Subgames are given by the set  $\{Q_{j0}^*, \dots, Q_{jm}^*\}$ . For each control  
515 there exists a unique Control Subgame solution  $Q_{j0}$ , which dictates that control  $j$  should not be used.

We define an optimal solution to the Knapsack problem as  $\Psi = \{Q_{j\lambda}^*\}, \forall j \in \{1, \dots, c\}, \forall \lambda \in \{1, \dots, m\}$ . A solution  $\Psi$  takes exactly one solution (i.e. equilibrium or cyber security plan) for each control as a policy for implementation. To

520 represent the cyber security investment problem, we need to expand the definitions for both expected damage  $S$  and effectiveness  $E$  to incorporate the Control Subgame solutions. Hence, we expand  $S$  such that  $S(Q_{j\lambda}, t)$ , which is the expected damage on target  $t$  given the implementation of  $Q_{j\lambda}$ . Likewise, we expand the definition of the effectiveness of the implemented solution on a given target as  $E(Q_{j\lambda}, t)$ . Additionally, we consider  $\Gamma(Q_{j\lambda})$  as the direct cost of implementing  $Q_{j\lambda}$ . If we represent the solution  $\Psi$  by the bitvector  $\bar{z}$ , we can then represent the 0-1 Multiple Choice, Multi-Objective Knapsack Problem as:

$$\begin{aligned} & \max_{\bar{z}} \min_{t_i} \left\{ \left\{ 1 - \sum_{j=1}^c \sum_{\lambda=0}^m E(Q_{j\lambda}, t_i) z_{j\lambda} \right\} I(t_i) T(t_i) \right\} \\ & \text{s.t. } \sum_{j=1}^c \sum_{\lambda=0}^m \Gamma(Q_{j\lambda}) z_{j\lambda} \leq B \\ & \sum_{\lambda=0}^m z_{j\lambda} = 1, \quad z_{j\lambda} \in \{0, 1\}, \forall j = 1, \dots, c. \end{aligned}$$

where  $B$  is the available cyber security budget, and  $z_{j\lambda} = 1$  when  $Q_{j\lambda}^* \in \Psi$ . In addition, we consider a tie-break condition in which if multiple solutions are viable, in terms of maximising the minimum, according to the above function we will select the solution with the *lowest cost*. This ensures that an organisation is not advised to spend more on security than would produce the same net effect.

### 6.3. Pure Knapsack Representation

A Pure Knapsack representation considers the method of solving the investment problem given that  $\mathcal{D}$  only considers the implementation of “whole” controls. This is to say that the solutions supplied to the Knapsack solver are representative of pure strategies solutions to the Control Subgames. To do this in a fair manner, we need to *include the indirect costs* of each cyber security plan (i.e. Control Subgame solution) into the calculation of benefit from each target. This is because the Hybrid representation has taken into account the impact of the indirect costs in the Control Subgames. We first extend the definition of indirect cost to incorporate Control Subgame solutions. Thus, we expand  $C$  such that  $C(Q_{j\lambda})$ , which is the indirect cost of  $Q_{j\lambda}$ . Thereafter, we can extend

the representation of the Knapsack problem to include the indirect costs as follows:

$$\begin{aligned}
& \max_{\vec{z}} \min_{t_i} \left\{ \left\{ 1 - \sum_{j=1}^c \sum_{\lambda=0}^m E(Q_{j\lambda}, t_i) z_{j\lambda} \right\} I(t_i) T(t_i) - \sum_{j=1}^c \sum_{\lambda=0}^m C(Q_{j\lambda}) z_{j\lambda} \right\} \\
& \text{s.t. } \sum_{j=1}^c \sum_{\lambda=0}^m \Gamma(Q_{j\lambda}) z_{j\lambda} \leq B \\
& \sum_{\lambda=0}^m z_{j\lambda} = 1, \quad z_{j\lambda} \in \{0, 1\}, \quad \forall j = 1, \dots, c.
\end{aligned}$$

#### 6.4. Comparison of Methods

To compare the Full Game, Hybrid and Pure Knapsack methods of decision support, we have developed a small case study that represents a small defence decision making problem that might be seen by system administrators. The problem creates an example with 7 controls and 13 vulnerabilities, created using a mapping from the SANS Critical Security Controls [25] combined with the CWE Top 25 Software Vulnerabilities [26]. The case study presented in this work considers a network separated into three different depths (i.e. Demilitarized Zone, Intranet, and Private Subnet). For this example, we consider the levels available to  $\mathcal{D}$  to consist of the quick win processes provided by SANS.

In comparing the damage at the weakest target provided by the Full Game and Hybrid method to the Knapsack representation, we can see in Fig. 2 that, in general, the Full Game representation will provide a better defence to the weakest target for low budget levels. This is due to the Full Game representation being able to combine all controls in a more flexible manner than either the Hybrid or Pure Knapsack, because the Full Game representation has no drawbacks to the implementation of the best controls in the most optimal configuration, which is still a restriction on the two methods that implement the 0-1 restriction of the Knapsack. Additionally, the Hybrid is occasionally able to offer a better solution than the Pure Knapsack, because the mixed strategies allow for certain control combinations to be used at a lower budget.

Each of the methods eventually reach a similar stable value, where although there is still damage expected from attacks against the system, the additional

cost to the performance of the system and users do not outweigh the benefit  
570 of implementing the additional control. This is owing to the impact that the  
indirect cost has on the decision-making process, where the cost is added to the  
damage to create the utility.

In the case where there are no indirect costs to implementing each control  
there is no trade-off to achieve a higher defence. This means that providing  
575 that an appropriate budget is available, the best defence will be purchased by  
all methods. In this case the solutions to the Control Subgames, in the Hybrid  
method, become the same as the pure strategies used in the Pure Knapsack and  
the resulting optimal solutions are the same.

We have found in terms of complexity of solutions provided, that the Pure  
580 Knapsack has solutions that can be followed intuitively as they only ever con-  
sider a single level of implementation. We can also see that the Hybrid method  
often uses pure strategies as in many cases the outcomes of the Control Sub-  
games lead to a single strategy at many levels. However, we find that there is  
an additional level of complexity in the comprehension of the strategies that are  
585 produced by the Full Game. Such complexity can potentially lead to strategies  
that can not easily be followed by a user to gain the most from the solution. In  
these cases, there is a risk that the solutions are not followed correctly and  
with security. This could lead to a potentially weaker defence over a seemingly  
weaker, but more easily interpreted solution.

590 In addition to the comparison above, we tested the example case presented  
by Rakes et. al. [10] to ensure that the optimisation algorithms used for solving  
the Hybrid and Knapsack problem were acting correctly. The study could be  
rebuilt using a reduced set of values from our model, which included the removal  
of indirect costs and the assumption of only one level of implementation for  
595 each control. In this example, we are able to obtain the same optimal set of  
countermeasures as the authors present in their work with a higher than 95%  
success rate on tested cases.

While we have seen that the Full Game representation of the problem is  
the most optimal on a small scale, the practicalities of operating such a system

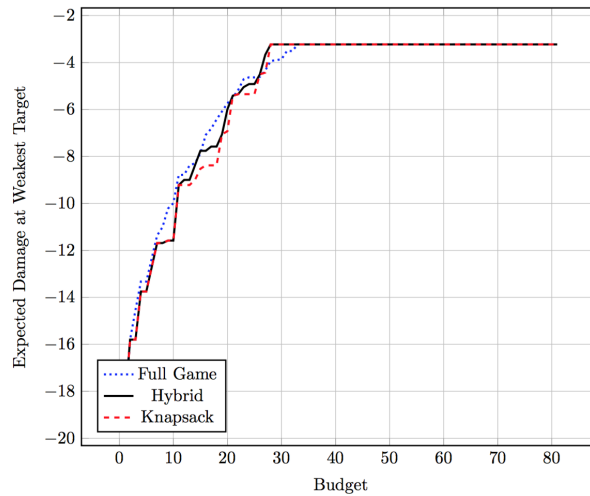

Figure 2: Comparison of Full Game, Hybrid and Pure Knapsack Methods of Decision Support.

600 on a larger scale is not possible. The next section details a more realistic case study consisting of 27 different controls acting on 36 different attacks, which is not feasibly solved by a Full Game representation. The challenge behind the Full Game representation of such a large case study, is that with multiple levels the number of pure strategies is of the magnitude  $10^{15}$ ; however, this is not a challenge that is faced by the Hybrid representation, which does not need to represent each pure strategy to calculate a solution, only up to the maximum number of levels in a Control Subgame.

605

## 7. Case Study

We have further used the ideas presented to develop a decision support tool that is capable of working on more realistic scenarios. The role of this tool is to be able to offer realistic actionable advice to organisations. The following represents a case study based on the design of a typical SME network, with the data used in the representation of the attacks, controls and costs for this case study available online [27].

610

Table 4: Case Study Vulnerability Type Distribution.

Vulnerability Type	No.	Vulnerability Type	No.
Software Errors: Data Interaction	8	Software Errors: Resource Management	8
Software Errors: Defence Flaws	6	Social Engineering: Targeted	3
Social Engineering: Untargeted	4	Network Vulnerabilities: Direct	3
Network Vulnerabilities: Indirect	4	-	-

615 *7.1. Case Study Composition*

The attacks have been built from a subset of the CVE [28] and CWE, which a conventional networked system would be expected to face, as well as a number of social engineering based attacks. The distribution of attacks amongst certain kinds can be seen in Table 4. The factors that are associated with the CWSS have been used to formulate the basis of the values for the vulnerabilities. There are two differences between the CWSS scoring system and the one used for this study. The first is the isolation of threat factors, since we are interested in the ability of an organisation to be able to identify their own concerns regarding the impact of a successful attack.

625 While a number of factors have been removed, a number of additional factors have been included to better differentiate different attacks. This has also provided a more generic insight into the decision making process of the attacker. Critically this involves the identification, availability and ease of the attacks for them to perform. This is done to indicate a partial reduction in risk of certain attacks, while making those that are easier to perform more enticing for the attacker. These are designed in such a way as to work not only with the attacker decision making in the Control Subgames, but also affect the designation of the potential weakest target in the optimisation. This aids in shifting some risk to the requirement of attacker capability.

635 The controls used in this case study are a set of actionable controls that a system administrator can implement to improve the security of their network. The controls have been derived from the SANS Top 20 critical security controls, separating the overarching control advice, to better reflect a single point of investment. The controls cover a variety of types of defensive strat-

Table 5: Case Study Control Type Distribution.

<b>Control Type</b>	<b>No.</b>	<b>Control Type</b>	<b>No.</b>
Security Software	4	Network Security Tools	7
System Configuration	8	Administration Tools	2
Policy Development	4	Education and Training	2

640 egypt, the distribution of which can be seen in Table 5.

The CVSS and CWSS both contain details regarding the efficiency of controls for protecting against a particular vulnerability. This internal definition of control effectiveness against each attack does not support our model for optimal defence spending. As such the effectiveness was redesigned to identify 645 which controls can mitigate which vulnerabilities, spread the efficiency amongst the viable levels, and interpret the viability of the control over the life of the solution, based either on complexity or frequency.

Each organisation is likely to have different configurations of systems and sizes and this makes defining the costs, in terms of a direct financial value, 650 difficult. An over specialised budget requirement would make using the tool infeasible in the real world. To remedy this we have normalised the direct costs of the control, such that the implementation of a number of controls operating at a conventional level from the advice has a cost of 1; an example of this is weekly patching.

655 The indirect costs are considered to be the importance that the organisation places on the day-to-day performance of the system, as well as the ability and willingness of staff to comply with any additional security policies. To do this, we define the indirect cost as an expected level of additional disruption caused in one of three categories: *System Performance*, any reduction in the speed and capability of the system to perform the related business tasks; *User Morale*, the 660 impact of the control on the behaviour of the system users; and *Re-Training*, the additional requirements for users of the system to be able to use the new control.

## 7.2. Experimental Comparison

The UK has published a set of guidelines that organisations, similar to the  
665 one in the case study, should comply with in order to reduce the risk of damage  
from cyber attacks [3]. The document called Cyber Essentials suggests a number  
of basic controls that organisations should implement to protect themselves  
from cyber attacks. The controls considered by Cyber Essentials are the use  
of firewalls and gateways, user access control, secure configuration, malware  
670 protection and patch management.

To perform this comparison, we have set a number of budget points in our  
control data, which represent different levels of investment. The first test case  
presents the scenario which accounts for the lowest price that allows for the  
implementation of Cyber Essentials at the lowest level. The second budget value  
675 allows for each of the controls from Cyber Essentials to be implemented at the  
highest level, while the final budget considers the availability of a higher level  
of investment beyond the advice offered by Cyber Essentials.

We are interested in investigating if controls in positions, 2, 4, 5, 7, 9, 20 and  
23 are recommended, as they relate to those suggested by Cyber Essentials. Both  
680 controls 5 and 7 relate to the implementation of firewalls, where control 5 is for  
network firewalls and control 7 relates to web application firewalls. Likewise  
controls 20 and 23 relate to User Access Controls, with User Access Controls  
representing the access policies concerning the network and devices in control  
20 and Account Management Control tools for users implemented in control 23.

## 685 7.3. Results

The following section describes the results obtained from calculating the op-  
timal defence strategy for the case study outlined. The results shown here are  
obtained using an implementation of the hybrid model solved using a genetic  
algorithm. The lowest budget shown in Table 6 chooses to implement four out  
690 of the five controls outlined in Cyber Essentials, with two of the controls being  
preferred at a higher level than the implementation of an additional control. The

optimal solution suggests implementing Patch Management and Network Firewalls at level two, with Anti-Malware and Secure Configurations both suggested at the most basic level. Under this limited budget, it is not suggested to have  
695 either Web Application Firewalls or User Access Controls, over the higher levels of other controls. In addition to the Cyber Essentials controls, the optimal solution suggests the implementation of an Incident Response Policy, which covers predominantly social engineering targets, with some minimal effect, but has a small cost.

700 When the budget is increased to 8, we see that the initial four controls in Cyber Essentials represented in the previous optimal solution are still represented, but with three controls recommended at a higher level. The optimal solution is to perform Patch Management at the highest level, such that it should be performed on demand. In this context it means that patches should  
705 be checked on a daily basis and implemented as soon as possible.

This budget brings in Account Management Control as a recommendation, which represents the last of the controls recommended by Cyber Essentials. The implementation recommends a strict account management control system, limiting the potential use of accounts, which reduces the risk of attacks  
710 being able to escalate privileges or access sensitive files with hijacked low level accounts. Additionally, we see the introduction of Web Application Firewalls in addition to the Network Firewalls that were suggested before, with a strict level of implementation. Since more of the vulnerabilities are covered to a higher level, the impact of the relatively cheap Incident Report Handling control has  
715 been removed as its addition has too minimal an impact to justify the cost. The controls outside of Cyber Essentials that are now considered are Automated Inventory Scanning and Management and basic Intrusion Detection Systems.

For a budget of 16, given by the solution 16a in Table 6, the solution differs from the previous budgets only in a few aspects. In terms of Cyber Essentials  
720 the optimal solution recommends implementing Network Firewalls at a lower level, however the solution still maintains the strict implementation of Web Application Firewalls. The other controls proposed by Cyber Essentials that

Table 6: Case Study Results.

Budget	Solution
3	[0, 2, 0, 1, 2, 0, 0, 0, 1, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 1, 0]
8	[1, 5, 0, 4, 2, 0, 3, 0, 3, 0, 0, 0, 0, 1, 0, 0, 0, 0, 0, 0, 0, 3, 0, 0, 0, 0]
16a	[4, 5, 0, 4, 1, 3, 3, 0, 3, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 3, 1, 0, 0, 0]
16b	[2, 5, 0, 3, 2, 2, 3, 0, 3, 0, 0, 0, 0, 0, 0, 1, 0, 1, 4, 0, 2, 0, 3, 1, 0, 0, 1]

had been recommended remain implemented at the same level as with a budget  
of 8. Inventory Management tools, are now implemented at a higher level than  
725 previously seen, moving from yearly inventory logging to weekly. The optimal  
solution now recommends the use of Intrusion Prevention Systems instead of  
Intrusion Detection Systems, which operate to cover more vulnerabilities than  
Network Firewalls, but were more costly to implement, making them less viable  
at lower budgets. Another additional control suggested at this budget level is  
730 the inclusion of yearly User Education and Training, which is used to improve  
a number of social engineering based attacks.

#### 7.4. Discussion

The results from the experimentation show with some consistency that the  
controls associated with Cyber Essentials are appropriate defensive measures  
735 for this kind of network. At low budgets, the system recommends implementing  
a number of controls that are suggested by Cyber Essentials, but not all of  
them, preferring to offer a more stable configuration of these controls over adding  
additional controls. At a higher budget, we see that the remaining controls are  
considered, with them being used beyond a basic level of implementation.

740 In all the cases presented the implementation of a rigorous Patching pol-  
icy is recommended where possible, as well as the presence of some Anti-  
malware, Firewalls and Secure Configuration. The main thing that can be ob-  
served from the data is that a combination of all of these four controls covers  
each of the vulnerabilities in the case study to some degree. This means that  
745 by increasing the level of any of these controls, there is guaranteed to be some  
observable reduction in damage on the system.

To follow this, one of the observations made throughout the experimentations the impact that the indirect costs have on the decision to implement certain security controls. The crucial component, is that as has been noted, a set of four  
750 controls are able to cover all the vulnerabilities to some level of efficiency; this means that the implementation of an additional control will only serve to reduce the impact of a vulnerability by a fraction of its maximum efficiency, while the costs for that control remain the same. As such there is a diminishing return on each control that you add to the system, which means that after certain  
755 values, it makes it more costly to the organisation to implement the control against the additional risk that they might mitigate.

Having seen how important the indirect costs are to calculating the optimality of the advice given, we have looked at the impact of a reduction in indirect costs. For this we have taken the highest budget level, which in the previous  
760 example was not using the whole of the budget due to indirect costs and have reduced the impact of indirect costs to 0.1 of their previous values.

The suggested implementation of controls, given by the solution 16b in table 6, changes the optimal strategy to introduce a series of new controls in addition to those seen previously. Even with a lower importance on indirect costs, we  
765 see that the optimal solution still recommends the implementation of the Cyber Essentials controls suggested in the initial tests.

Additional government advice suggest the use of Whitelisting, which is not seen in the initial solutions. While whitelisting of both applications (control 19) and websites (control 21) are able to prevent a number of cyber attacks by preventing access, they have a high negative impact on the daily operations of the  
770 organisation. This results in a high indirect cost, which reflects their exclusion in the previous optimal solutions. However, with relaxed indirect costs, the negative impact now no longer outweighed by the benefit, which now represents their inclusion in the optimal solution. The same advice recommends penetration testing if possible if you are expecting to be at risk of more long term  
775 attacks, this control is also recommended in the solution with revised indirect costs.

## 8. Conclusions

In this paper we have presented an analysis of a hybrid game-theoretic and  
780 optimisation approach to the allocation of an SME's cyber security budget. For  
this purpose, we have compared three different approaches to allocating this  
budget by using a decision support tool. In terms of understanding the solu-  
tions, we have found that with a relatively small case study the results can be  
interpreted in a relatively simple manner. However, we are concerned that for a  
785 larger case study the Full Game representation would create solutions that are  
too complex to be interpreted in an accurate manner so that they could result  
in a weaker defence. This work also highlights the impact, which the indirect  
costs have on the problem of cyber security budget allocation. Considering the  
downside that the implementation of a control may have on the organisation is  
790 important, since it can better capture the decision-making process required for  
investment. The results presented in this paper demonstrate how those indirect  
costs are able to influence the optimal decision in cyber security budget alloca-  
tion. We aim to use the work presented in this paper to inform models of attacks  
against a system. These games model the interactions between an attacker and  
795 defender at the *point of attack*, and during an ongoing attack. To do this we will  
consider multi-stage games which represent the stages of an attack and recov-  
ery in a system. In addition, we aim to investigate cyber security investments  
by following a multidisciplinary approach that combines economic, behavioural,  
societal and engineering insights. Our end goal is to achieve increased societal  
800 resilience to cyber security risks through more efficient and effective institutional  
and incentives structures. Last but not least, in future work we aim to investi-  
gate how cyber insurance [2] can influence cyber security investment decisions.
