35 **Running title:** iDNA from leeches for biomonitoring

36 **Abstract**

37 The application of metabarcoding to environmental and invertebrate-derived DNA (eDNA
38 and iDNA) is a new and increasingly applied method for monitoring biodiversity across a
39 diverse range of habitats. This approach is particularly promising for sampling in the
40 biodiverse humid tropics, where rapid land-use change for agriculture means there is a
41 growing need to understand the conservation value of the remaining mosaic and degraded
42 landscapes. Here we use iDNA from blood-feeding leeches (*Haemadipsa picta*) to assess
43 differences in mammalian diversity across a gradient of forest degradation in Sabah,
44 Malaysian Borneo. We screened 557 individual leeches for mammal DNA by targeting
45 fragments of the 16S rRNA gene and detected 14 mammalian genera. We recorded lower
46 mammal diversity in the most heavily degraded forest compared to higher quality twice
47 logged forest. Although the accumulation curves of diversity estimates were comparable
48 across these habitat types, diversity was higher in twice logged forest, with more taxa of
49 conservation concern. In addition, our analysis revealed differences between the community
50 recorded in the heavily logged forest and that of the twice logged forest. By revealing
51 differences in mammal diversity across a human-modified tropical landscape, our study
52 demonstrates the value of iDNA as a non-invasive biomonitoring approach in conservation
53 assessments.

54 **Keywords:** Invertebrate-derived DNA, molecular biomonitoring, Haemadipsidae,
55 biodiversity, land-use change, Borneo

56 **Introduction**

57 Tropical ecosystems are under pressure from deforestation (Hansen et al., 2013) and other
58 anthropogenic activities driving forest degradation (Lewis, Edwards, & Galbraith, 2015). The
59 removal of trees, and the associated damage from timber extraction, causes lasting changes
60 to vegetation structure and microclimate, with knock-on consequence for species diversity
61 (Blonder et al., 2018). For example, microclimatic extremes are more frequent in logged
62 forests than in older growth forests (Blonder et al., 2018; Hardwick et al., 2015; Jucker et al.,
63 2018). In addition, to altering floral and faunal community composition (Laurance et al.,
64 2018; Wilkinson, Yeo, Heok, Hadi, & Ewers, 2018), logged forests can show changes in
65 diverse ecosystem functions, including litter decomposition, predation and seed dispersal
66 (Bovo et al., 2018; Robert M. Ewers et al., 2015). As a result, such forests show lower
67 resilience to numerous local and climatic stressors (Struebig et al., 2015) and are at greater
68 risk of conversion to commodity agriculture (Edwards et al., 2011).

69 Despite the well-known negative effects of forest degradation on ecosystem processes, there
70 is evidence that these degraded habitats can still support biodiversity and have considerably
71 greater conservation value than alternative agricultural landscapes (Deere et al., 2017;
72 Gibson et al., 2011). Even within highly degraded forest, animal community composition
73 tends to be more similar to forest than it is to agricultural plantations (Gray, Slade, Mann, &
74 Lewis, 2014; Wearn et al., 2017). Within heavily logged forest, for example, forest remnants
75 have been shown to be important for birds (Mitchell et al., 2018) and invertebrates (Gray et
76 al., 2014). These and other studies of how land-use change relates to biodiversity have
77 increasingly utilised data generated by LiDAR, an approach that allows new and improved
78 opportunities to quantify forest structure and microclimatic variables across spatial scales
79 (Asner et al., 2018; Deere et al., 2020; Seaman et al., 2019).

80 In recent years, the toolkit for biodiversity monitoring has expanded from solely field-based
81 methods to also encompass molecular techniques. In particular, advances in sequencing now
82 allow for the routine metabarcoding of environmental DNA (eDNA) samples, thereby
83 revolutionizing molecular ecology. One such area that has seen rapid progress is the use of
84 animal-feeding invertebrate species as samplers of vertebrate diversity. Invertebrate

85 samplers have tended to be haematophagous species, of which arguably the most popular
86 have been leeches (Abrams et al., 2019; Drinkwater et al., 2018; Fahmy, Ravelomanantsoa,
87 Youssef, Hekkala, & Siddall, 2019; Schnell et al., 2018; Tessler et al., 2018; Weiskopf et al.,
88 2017) and dipteran flies (Calvignac-Spencer et al., 2013; Gogarten et al., 2019; Hoffmann et
89 al., 2018; Kocher, de Thoisy, Catzeflis, Valiere, et al., 2017).

90 To date, invertebrate-derived DNA (iDNA) has been widely utilised to obtain inventories of
91 mammals and other vertebrate groups from tropical regions (e.g. Fahmy et al., 2019;
92 Gogarten et al., 2019; Kocher, de Thoisy, Catzeflis, Valière, et al., 2017), however, these have
93 tended to focus on opportunistic invertebrate collection methods and comparisons of
94 diversity across geographic regions (Schnell et al., 2018; Tessler et al., 2018). Yet since iDNA
95 (and eDNA) can allow genetic confirmation of species presence without the need for actual
96 observations, it can also complement more conventional monitoring based on, for example,
97 camera trap surveys, with associated savings in fieldwork costs (e.g. Leempoel, Hebert, &
98 Hadly, 2019; Weiskopf et al., 2017). Abrams et al. (2019) have extended this further by
99 analysing data from spatially matched iDNA and camera traps using an occupancy modelling
100 framework and found that while both methods resulted in similar accumulation rates, the
101 latter gave higher absolute species richness values. These authors also demonstrated that
102 estimates of occupancy and detection probability varied depending on host species but also
103 depended on leech type, with tiger leech (*Haemadipsa picta*) samples resulting in higher
104 detection and occupancy probabilities compared to brown leeches (*Haemadipsa zeylanica*)
105 (Abrams et al., 2019).

106 A further consideration of using iDNA is whether habitat has an effect on the efficacy of the
107 invertebrate used for sampling (the so-called 'invertebrate sampler'). This may be
108 particularly pertinent in the context of land use change, where small-bodied invertebrates
109 may be more sensitive to local conditions than the vertebrates for which they are being used
110 to assay. It is not known, for example, whether local microclimate conditions will alter the
111 foraging behaviour of invertebrate samplers, and thus their utility for comparing vertebrate
112 diversity across habitats. Among the popular samplers are terrestrial leeches of the family
113 Haemadipsidae, which are restricted to humid habitats and adversely impacted by the drier

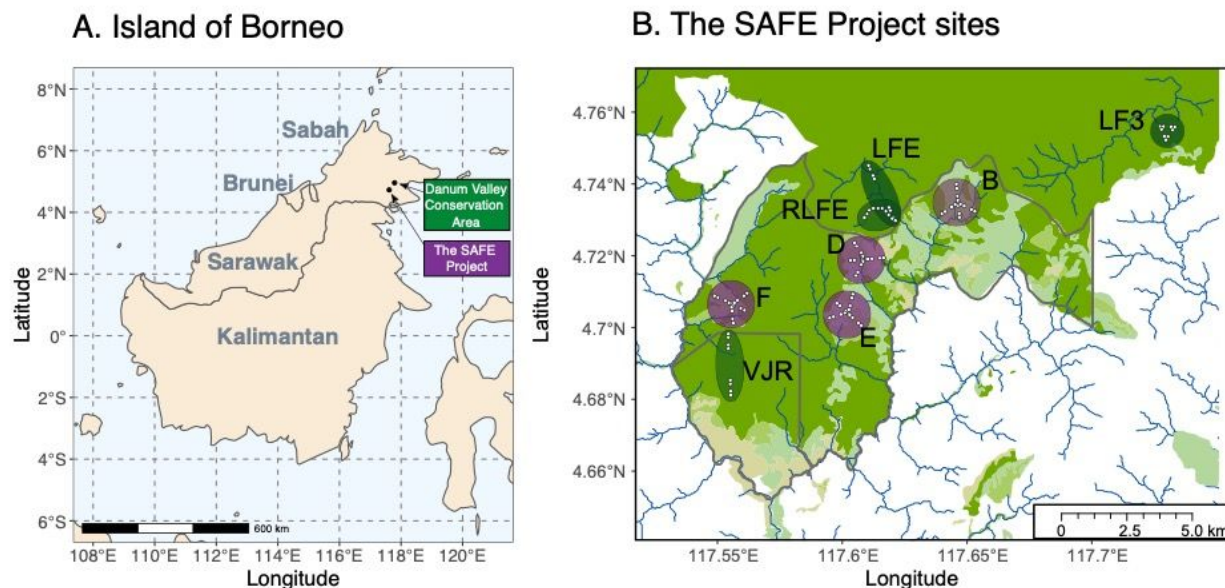

114 conditions arising from forest degradation (Hardwick et al., 2015; Jucker et al., 2018).
115 Previously we showed that forest structure affects the distributions of two congeneric
116 haemadipsid leech species in logged forest (Drinkwater et al., 2019), yet it is not known
117 whether such habitat preferences have additional implications for the detection of mammals.

118 Here we apply iDNA to assess the impact of habitat degradation on mammal diversity across
119 a tropical landscape. Additionally, we test whether landscape-scale variation in mammal
120 diversity can be explained by temperature and humidity, which could suggest that detected
121 patterns are mediated by leech responses to microclimate. To achieve this, we combined
122 repeated surveys with a standardised collection protocol for tiger leeches (*Haemadipsa*
123 *picta*) across a degraded forest landscape in Malaysian Borneo. In this region, unsustainable
124 logging practices coupled with land conversion for oil-palm agriculture have led to the
125 depletion of ancient dipterocarp forests, leaving behind managed landscapes that are
126 fragmented and degraded (Gaveau et al., 2014).

127 **Materials and methods**

128 *Study design and sample collection*

129 Sampling was undertaken at The Stability of Altered Forest Ecosystems (SAFE) Project,
130 Sabah, Borneo. This landscape has experienced varying degrees of logging disturbance since
131 the 1970s and now comprises a mosaic of historically twice logged forest and more heavily
132 degraded forest (Ewers et al., 2011). To understand the impact of this habitat degradation
133 on mammal diversity through the use of iDNA, we analysed individuals of the terrestrial
134 blood feeding tiger leech, *Haemadipsa picta*, collected at fixed locations across the SAFE
135 landscape during a wet season between September and December 2016 (Table 1, Figure 1).
136 The fixed locations were long-term monitoring plots established by the SAFE project, which
137 are grouped in larger sites, based on proximity (Ewers et al., 2011). We initially aimed to
138 sample from plots in all of the 14 sites, excluding the sites established with oil palm
139 plantations (OP1-3, Ewers et al., 2011). However, in reality only plots in 8 sites could be
140 sampled as a result of permit issues or access, e.g. bad roads. Repeated surveys were
141 conducted within established 25m² plots by searching the leaf litter and understory for
142 twenty minutes and collecting *H. picta* individuals and storing them in RNA Later (Qiagen)
143 or subsequent molecular analyses (see Drinkwater et al., 2018). In addition, to extend habitat
144 comparisons to pristine old growth forest, we also undertook equivalent surveys at the
145 Danum Valley Conservation Area (DVCA), approximately 40 km away. Within each site, up
146 to four repeat surveys were conducted at 8-12 plots over the season. Sites were classified
147 into three levels of degradation based on logging history (Ewers et al., 2011): (i) old growth,
148 (ii) twice logged, and (iii) heavily logged, with the latter experiencing recent salvage logging
149 (for definitions of habitat type see Supplementary Table S1).

150

151 **Figure 1.** (A) Map of Borneo showing different regions, with Danum Valley Conservation
 152 area and the SAFE project locality in Sabah marked as black circles. (B) SAFE study landscape
 153 showing the 25m² plots (small white points) where leech samples were collected within the
 154 two habitat types: twice logged sites – LFE, LF3, RLFE & VJR (large green shading) and
 155 heavily logged sites = B, D, E & F (large purple shading).

156 *DNA extraction, PCR amplification and library pooling*

157 To extract DNA, we incubated single whole leeches in lysis buffer and proteinase K overnight,
 158 following Drinkwater et al., (2018). After the initial digestion step, lysates from each leech
 159 were pooled by mixing 100 μ L of site-matched samples, specifically leeches collected from
 160 plots within the same site, (Supplementary Table S2 has full details of leech pools). To
 161 increase DNA yield we modified the DNA extraction protocol from Drinkwater et al., (2018)
 162 with the addition of an extra lysis step: 200 μ L of buffer AL from DNeasy Blood and Tissue
 163 kit (Qiagen) to a 200 μ L subsample of each pooled digest which was then incubated for 15
 164 minutes at 56°C. We then mixed in an additional 200 μ L of 100% ethanol following the
 165 QiaQuick PCR purification protocol (Qiagen, UK) but with reduced centrifuge speeds
 166 (6000g). For this study, we define a sample as a mix of iDNA from site-matched leeches.
 167 Alongside each batch of the extractions we also conducted at least one extraction control (i.e.
 168 a blank sample that contained all of the reagents minus the tissue).

169 To minimise the risk of over-inflation, leading to erroneously high diversity estimates, we
170 used uniquely tagged, matching primers for each leech sample (Binladen et al., 2007) and
171 PCR reactions were conducted in triplicate. The primers we used were mammal-specific with
172 a target of a short (~95 bp) fragment of the 16S rRNA gene (Taylor, 1996). To 1 µL of DNA
173 template we added 0.2mM of 10x buffer, 2.5mM MgCl₂, 1 unit DNA polymerase (AmpliTaq
174 Gold, Applied Biosystems), 0.2mM dNTP mix (Invitrogen), 0.5mg/mL BSA, 0.6µM of the
175 forward and reverse tagged primer resulting in a final volume of 25 µL. The cycling profile
176 was as follows 1) 95^oC for 5 minutes, 2) 40 cycles of 95^oC for 12 seconds, 59^oC for 30 seconds
177 and 70^oC for 20 seconds and 3) a final extension time of 7 minutes at 70^oC. Negative PCR and
178 extraction controls were included in each batch of reactions and treated the same. Products
179 were checked using 2% agarose gels and those reactions which showed amplification were
180 mixed into amplicon pools (only containing unique tags) for a single-tube library build
181 (Carøe et al., 2017). The amplicon pools were sequenced in two batches, one at Queen Mary
182 University of London's Genome Centre and the other at the Danish National
183 High-Throughput Sequencing Centre (University of Copenhagen), both with 150bp paired-
184 end chemistry with an Illumina MiSeq. The samples used in this study were multiplexed with
185 other biological samples to increase complexity and thus accuracy of base calling.

186 *Quality control, filtering and assigning sequences*

187 Once sequenced, read pairs were merged using AdapterRemoval version 2 (Schubert,
188 Lindgreen, & Orlando, 2016). Data were demultiplexed based on nucleotide tag and library
189 index combination using a modified version of DAME and collapsed to unique sequences
190 (<https://github.com/shyamsg/DAME>, Zepeda Mendoza, Bohmann, Carmona Baez, & Gilbert,
191 2016). To increase certainty in our assignments and to account for PCR stochasticity, we
192 retained only unique sequences which appeared in a minimum of two out of the three PCR
193 replicates. While this 'relaxed restrictive' approach (Alberdi, Aizpurua, Gilbert, & Bohmann,
194 2017) lowers the overall detected diversity, it reduces bias and numbers of false positives
195 from contamination and artefactual sequences. Next we filtered the sequences and only
196 retained those sequences represented by more than 10 reads. To assign taxonomy we
197 performed *in silico* PCR using the program ecoPCR (Ficetola et al., 2010). To do this, we

198 compared the 16S primer against all mammal sequences on GenBank (NCBI), allowing for a
199 maximum of three mismatches between the query sequence and the primers. We generated
200 an ecoPCR database of all complementary sequences that could theoretically be amplified by
201 our primer set. Using this database we mapped the unknown iDNA sequences using the
202 *ecotag* command in OBITools package (Boyer et al., 2016) with a minimum identity of 0.95.
203 We removed any sequence with an assignment above genus-level, as well as any assignment
204 to a non-native or geographically implausible mammal, and any human contaminant
205 sequence. We only assigned sequences to a species-level for those mammal genera for which
206 only one species representative is known to occur in Sabah. Within each leech pool, multiple
207 assignments to the same taxon were collapsed, resulting in occurrence data or presence-
208 only, a common practice given the uncertainty of the link between sequence count and
209 species abundance in the context of metabarcoding studies (Deagle et al., 2018; Elbrecht &
210 Leese, 2015).

211 *Accumulation of diversity*

212 The successful detection of a mammal from leech-ingested iDNA requires both that it was
213 fed upon by the leech, and that its DNA is sufficiently intact for PCR amplification, and thus
214 iDNA will likely underestimate actual diversity in a given habitat. For this reason, to estimate
215 the alpha diversity of mammals based on the incidence of taxa we used the Chao2 estimators,
216 which accounts for potential under sampling (Gotelli & Colwell, 2011). Diversity
217 accumulation curves were generated for each forest type within a Hill number framework
218 (Hill, 1973), using the “iNEXT” package in R (Hsieh, Ma, & Chao, 2016) which uses the
219 random acquisition of samples (Chao et al, 2014). Hill numbers are a way of unifying and
220 generalising the commonly used (but difficult to interpret) diversity indices, such as
221 Shannon and Simpson indices, into more meaningful units, for example the effective number
222 of species, or the number of equally-abundant species needed to produce the same diversity
223 value (Chao et al., 2014) or, for iDNA, equally abundant operational taxonomic units or OTUs
224 (Alberdi & Gilbert, 2019). Different values of the scaling parameter, q , change the Hill

225 number order of diversity based on sensitivity to rare species in the community. Thus, the
226 most commonly used values, $q = 0, 1, 2$, are, respectively, equivalent to species richness, the
227 exponential of the Shannon index, and the inverse of the Simpson index (see Chao et al.,
228 2014). The use of Hill numbers is recommended when incomplete sampling is expected
229 (Chao et al., 2014). In iDNA-derived estimates of diversity, additional sources of sample
230 incompleteness can arise from the degradation of mammal DNA following digestion of the
231 blood meal by the leech (Schnell, Thomsen, Wilkinson, Jensen, et al., 2012), and the
232 stochasticity of a PCR-based amplification. Sample-based accumulation curves were
233 generated for each habitat type and for the three orders of diversity ($q = 0, 1, 2$), and curves
234 extrapolated to double the sample size of the observed value, following the maximum
235 recommended extrapolation in Chao et al., (2014). Curves were plotted using 84%
236 confidence intervals (CIs), which have been demonstrated to be equivalent to an alpha value
237 of 0.05 when testing for significant differences between curves (MacGregor-Fors & Payton,
238 2013; Payton, Greenstone, & Schenker, 2003). Research has shown that CIs can be
239 overlapping by as much as half of one of the upper or lower intervals and still be equivalent
240 to $p = 0.05$ (Cumming, 2009). Accumulation curves with the more traditional 95% interval
241 are shown in Supplementary Figure S1 for comparison. Using the more common rarefaction
242 method, we calculated the diversity and sample coverage at each order of q (0, 1, 2) based
243 on the smallest samples size with the *estimateD* function in iNEXT. These analyses were
244 produced using “vegan” (Oksanen et al., 2017) and the “iNEXT” packages (Hsieh et al., 2016)
245 in R (R Core Team, 2019) and figures were produced using “ggplot2” (Wickham, 2016) and
246 “ggpubr” (Kassambara, 2020).

247 *Community composition across a habitat gradient*

248 We used non-metric multidimensional scaling (NMDS) to visualise the community structure
249 among sites of iDNA-detected taxa. We used Chao’s coefficients as our measure of
250 dissimilarity between sites since this index accounts for the effect that undetected species
251 have on the whole species pool and outperforms other dissimilarity indices when a large

252 number of rare species are present in the sample (Chao, Chazdon, Colwell, & Chen, 2005).
253 We ran the NMDS using the occurrence of taxa at each site for different numbers of axes ($k =$
254 $2, 3, \& 4$) and assessed the resulting stress using screeplots. We present the NMDS with 95%
255 confidence intervals around the groups of sites within each habitat classification. To test for
256 differences in variance between the habitat types, we used a permutational multivariate
257 analysis of variance (PERMANOVA) All models were run for 9999 permutations and
258 constrained by site identity to reflect the study design. All NMDS and PERMANOVA analyses
259 were conducted using the *vegan* package (Oksanen et al., 2017) and plots were generated
260 using “*ggordiplot*” (Quensen, 2018), in R.

261 *Microclimate variables*

262 To investigate the effects of microclimate on the detection of mammals through leech iDNA
263 we considered four variables: maximum temperature, mean temperature, maximum vapour
264 pressure deficit (VPD), and mean VPD, each of which was available for the entire SAFE
265 landscape at a 50×50 m resolution. These variables were generated for our key sites at SAFE
266 by combining temperature and VPD measurements obtained from a landscape-scale
267 network of 120 microclimate dataloggers with high-resolution maps of topography and
268 canopy structure derived from airborne LiDAR (see Jucker et al., 2018, for full details). The
269 four variables were extracted from the microclimate surface generated in Jucker et al.,
270 (2018), using the coordinates from the centre of each of the 25m^2 plots. Values for Danum
271 Valley Conservation Area (Old Growth forest) were extracted using the same approach, but
272 from coordinates at fixed sites along rivers within the DVCA closest to the plots where we
273 sampled. Values are shown in Supplementary Figure S2 with points plotted using the
274 function *geom_jitter* in the R package “*ggplot2*” to aid visualisation on the horizontal axis.

275 *Models of habitat type and microclimate on diversity*

276 Since all four microclimate variables described (see above) co-vary, we conducted a
277 principal component analysis (PCA), to identify the most relevant to include in the final

278 model of iDNA richness. This showed that sites cluster based on habitat type, and that mean
279 VPD and mean temperature showed the greatest orthogonal difference (Supplementary
280 Figure S3). Thus, to distinguish between warm/cool and wet/dry sites, we continued the
281 analysis using these two mean microclimate variables. We tested two response variables,
282 alpha diversity using a Poisson GLM, and the exponent of Shannon's diversity index (Hill
283 number where $q = 1$) with a normal distribution. We included mean temperature and mean
284 VPD as continuous fixed effects, and habitat type with three levels (old growth, twice logged
285 and heavily logged) as a categorical effect. As the number of leeches collected per site varied,
286 we included this variable as an offset term in all models, which specifies the amount of
287 variation in the response variable that can be attributed to the offset term (Crawley, 2007):
288 e.g. the number of leeches. This method sets the regression coefficient to 1 and allows the
289 diversity of a sample to be calculated given the number of leeches sequenced. As a null model
290 for comparison, we removed all terms except the offset.

291 Using an AIC approach, we generated every potential model, from the full to the null model,
292 and calculated the ΔAIC values and AIC weight. We then removed models which made up
293 less than 5% of the cumulative weight. To summarise the relative importance of each
294 variable, we calculated a weighted proportion of best fitting models which retained the
295 variable of interest, as the cumulative AIC weight divided by the maximum AIC weight of the
296 model set. All model analyses were conducted in base R and with "bbmle" (Bolker & Team,
297 2014), "broom" (Robinson & Hayes, 2020), and the PCA and figure (Supplementary Figure
298 S3) were generated using base R (R Core Team, 2019) and "factoextra" (Kassambara &
299 Mundt, 2020).

300 **Results**

301 *Sequence filtering and taxonomic identification*

302 Following filtering steps, all samples above a genus-level were removed with the exception
303 of a single hit to the Felidae family, which occurred as a high copy number. Since there are
304 multiple felid genera in Borneo, we retained the family-level designation. Additionally, a
305 large number of unique sequences (296 of prefiltered 1590) were assigned to the genus *Sus*.
306 Although the domestic pig (*Sus scrofa*) DNA can often be a source of laboratory
307 contamination in eDNA studies, only 93 of these 296 were assigned directly to *S scrofa* by
308 OBITools and removed. Given that *S. scrofa* does not occur naturally in Borneo, is not farmed
309 in the study area, and did not occur in the PCR negative controls, we assigned the remaining
310 203 unique sequences to the only native pig species Bornean bearded pig (*Sus barbatus*).
311 This taxon is the most abundant large-bodied mammal at the SAFE study site, and is
312 commonly recorded in large groups by camera traps (Deere et al., 2017).

313

314 After comparing the filtered reads to the ecoPCR database we identified 1362 unique
315 sequences. We collapsed these by taxon and leech pool, resulting in 92 detections across 57
316 leech pools with an average of 1.6 detections per pool (range = 1 – 5, median = 1, Table 1).
317 The mean number of individual leeches per pool was 9.8 (range = 5 – 11, median = 10). The
318 detections were assigned to ten mammal families (Table 2), which could further be identified
319 as belonging to 14 genera (with the exception of the Felidae hit). Of these 14, nine could be
320 confidently assigned to species-level based on the knowledge of a single species known to
321 occur within Sabah. An additional four genera each contain two species that co-occur on
322 Borneo, and were thus only assigned to genus. These taxa, along with their common names,
323 are: *Macaca fascicularis* (Long-tailed macaque) and *M. nemestrina* (Southern pig tailed
324 macaque), *Muntiacus muntjac* (Common Southern red muntjac) and *M. atherodes* (Bornean
325 yellow muntjac), *Tragulus napu* (greater mousedeer) and *T. kanchil* (Lesser mousedeer), and
326 *Hystrix brachyura* (Malay porcupine) and *H. crassispinis* (thick-spined porcupine).

Table 1. Site classification and sample sizes. At each site, we grouped individual leeches (3-11, mean = 9, median = 10) into pools prior to sequencing. Each site was then assigned a broad forest type classification and the number of mammal detections from is given.

| Site | Habitat type | Individuals | Pools | Detections |
|-------------|---------------------|--------------------|--------------|-------------------|
| OG | Old growth | 114 | 12 | 16 |
| VJR | Twice logged | 27 | 3 | 5 |
| LF3 | Twice logged | 99 | 10 | 23 |
| LFE | Twice logged | 130 | 13 | 22 |
| RLFE | Twice logged | 19 | 2 | 2 |
| B | Heavily logged | 70 | 7 | 12 |
| D | Heavily logged | 60 | 6 | 13 |
| E | Heavily logged | 28 | 3 | 5 |
| F | Heavily logged | 10 | 1 | 5 |

Table 2. Taxonomic assignments to order-, family-, genus- and, where possible, species-level identities. All assignments could be made to at least genus apart from one, an unknown Felidae, which is indicated by a *. The number of occurrences of each assignment is given and the number of sites it was found.

| Order | Family | Genus | Species | Common name | Occurrences | Sites |
|-----------------|-----------------|---------------------------|--------------------------------|--------------------------|-------------|-------|
| Cetartiodactyla | Cervidae | <i>Muntiacus</i> | | Muntjac | 8 | 6 |
| | | <i>Rusa</i> | <i>Rusa unicolor</i> | Sambar deer | 21 | 9 |
| | Suidae | <i>Sus</i> | <i>Sus barbatus</i> | Bearded pig | 24 | 8 |
| | Tragulidae | <i>Tragulus</i> | | Mouse deer | 6 | 2 |
| Carnivora | Felidae* | | | Asian wild cat species | 1 | 1 |
| | Ursidae | <i>Helarctos</i> | <i>Helarctos malayanus</i> | Sun bear | 2 | 1 |
| | Viverridae | <i>Arctogalidia</i> | <i>Arctogalidia trivirgata</i> | Small toothed palm civet | 1 | 1 |
| | | <i>Hemigalus</i> | <i>Hemigalus derbyanus</i> | Banded civet | 1 | 1 |
| | | <i>Paguma</i> | <i>Paguma larvata</i> | Masked palm civet | 1 | 1 |
| | <i>Viverra</i> | <i>Viverra tangalunga</i> | Malay civet | 5 | 4 | |
| Pholidota | Manidae | <i>Manis</i> | <i>Manis javanica</i> | Sunda pangolin | 1 | 1 |
| Primate | Cercopithecidae | <i>Macaca</i> | | Macaque | 2 | 2 |
| Proboscidea | Elephantidae | <i>Elephas</i> | <i>Elephas maximus</i> | Elephant | 1 | 1 |
| Rodentia | Hystricidae | <i>Hystrix</i> | | Porcupine | 16 | 6 |
| | | <i>Trichys</i> | <i>Trichys fasciculata</i> | Long-tailed porcupine | 2 | 2 |

329 *Accumulation of diversity across habitat types*

330 Twice logged forest sites had a greater estimated diversity where $q = 0$ (species richness)
331 compared to the heavily logged forest, but this is overlapping with the old growth habitat.
332 Where $q = 2$ both logged habitat types have higher estimates of diversity than the old growth
333 forest (Figure 2). When sample sizes were rarefied to the smallest sample size, the old
334 growth habitat had the lowest diversity estimates at all three values of q , but the confidence
335 intervals are all overlapping (Figure 2).

336

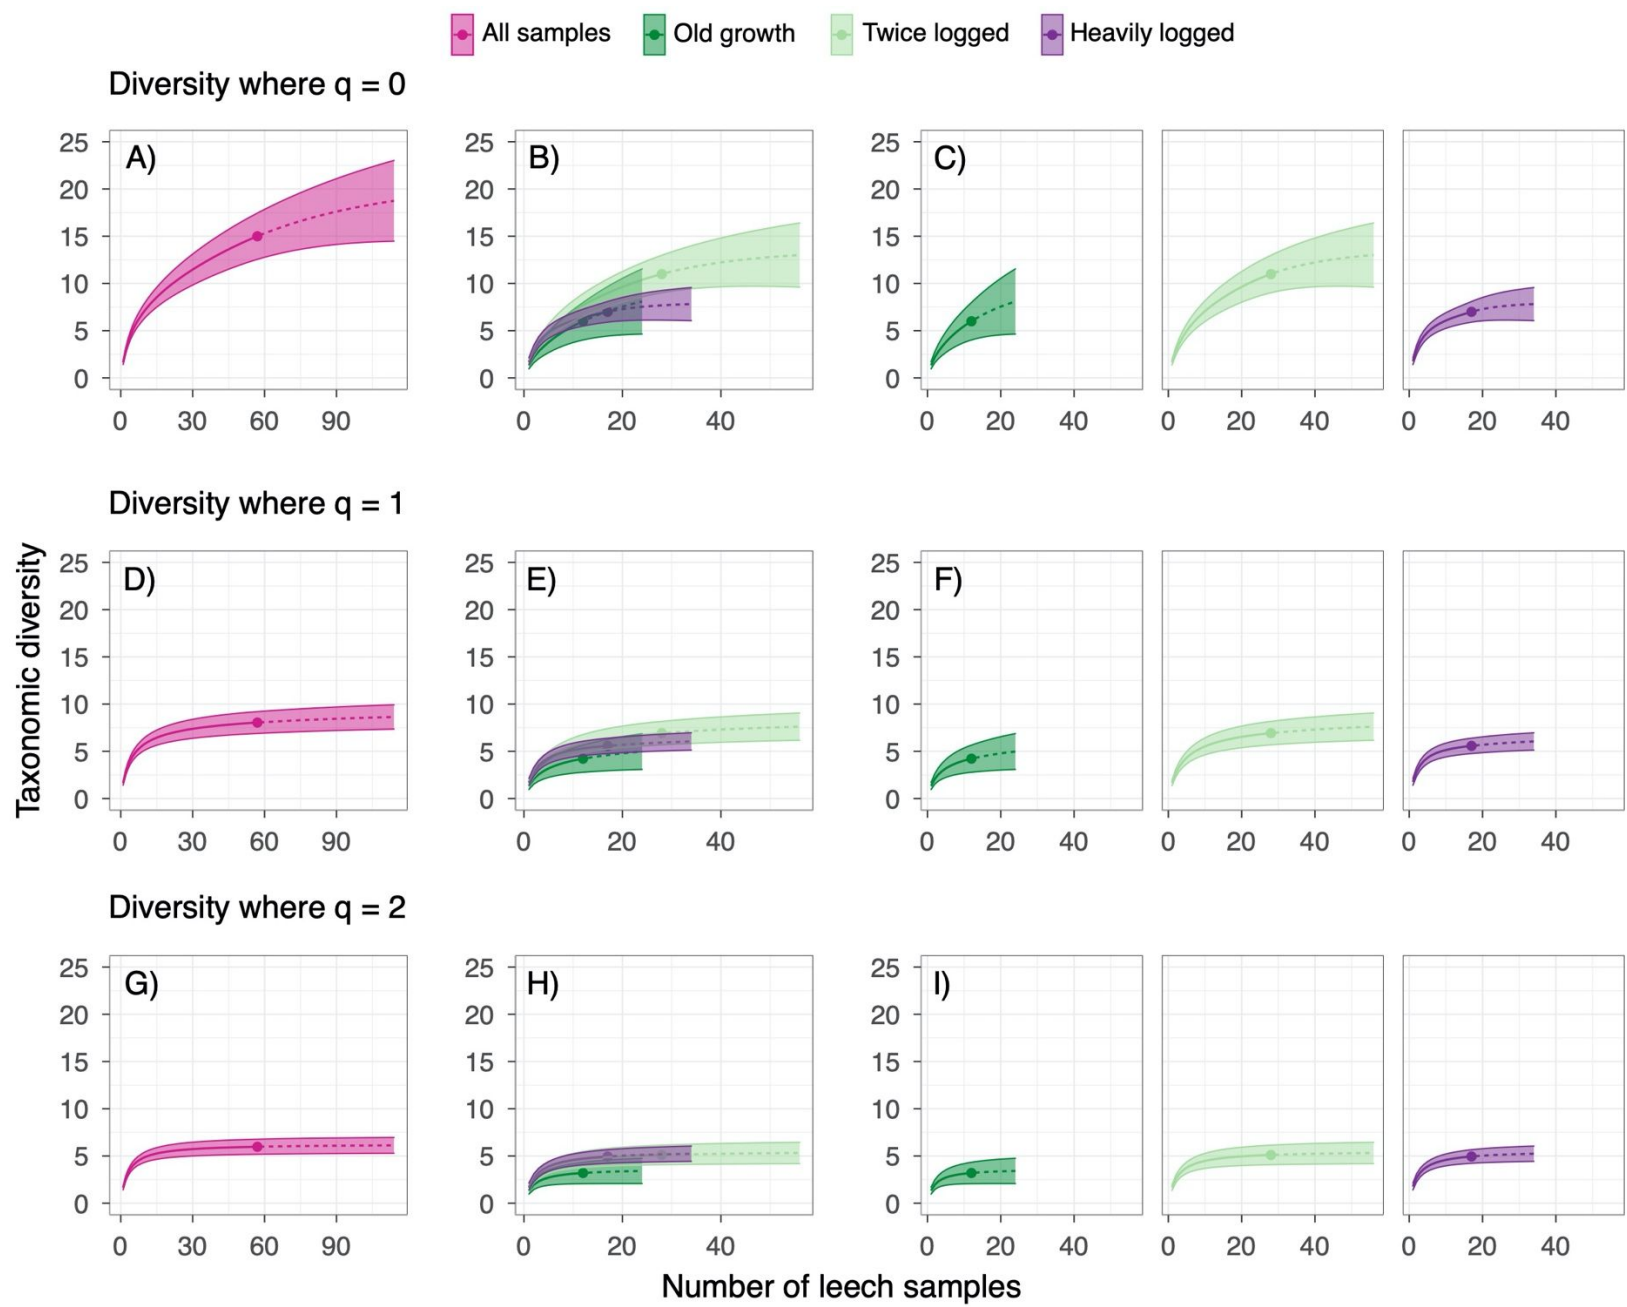

337 When $q = 0$, twice logged forest showed more rapid accumulation of mammal genera
338 compared to the heavily logged forest, but values fell within the confidence intervals of the
339 curve for old growth forest (Figure 3B). All habitat types overlapped at $q = 1$ although old
340 growth forest was lower than the other habitats (Figure 3E), whereas at $q = 2$ the former
341 habitats overlapped with each other but did not overlap with the lower accumulation curve
342 of the old growth (Figure 3H). This may indicate that the observed differences between the
343 two degraded habitats are driven by unevenness. The curves for all three habitats are
344 approaching an asymptote where $q = 1$ and 2 (Figure 3D, E, G and H).

345

346 **Figure 2.** Plot of the estimated asymptotic diversity estimates, solid bars and the rarefied
 347 diversity values, open bars for diversity where $q = 0, 1, 2$, for each of the habitat types. The
 348 samples are rarefied to the smallest sample which is for the old growth habitat, $n = 12$.

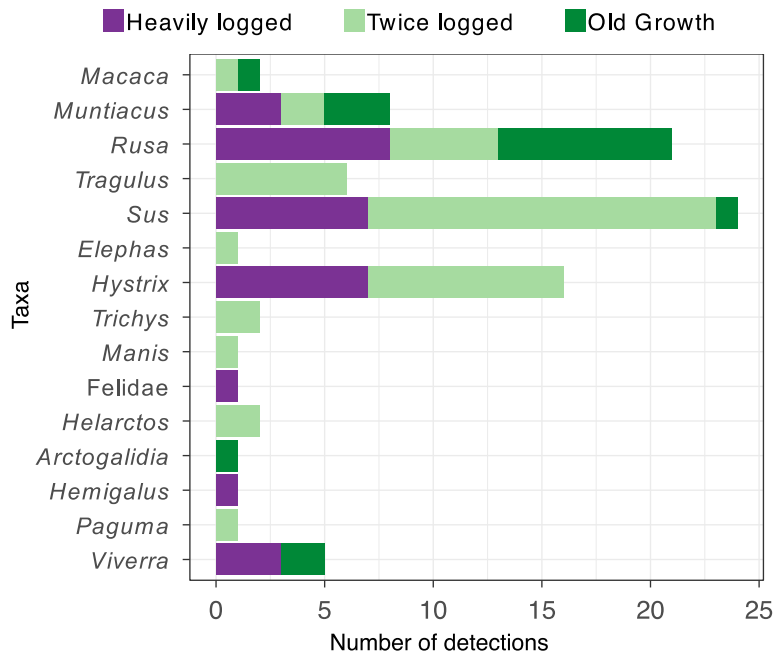

349 Error bars shown are the 95% confidence intervals.

351 **Figure 3.** Diversity accumulation curves at the genus-level comparing the effect of increasing leech samples on the detected
352 diversity within different habitat types. Curves are calculated using three orders of hill numbers, $q = 0, 1$ and 2 - equivalent to
353 species richness, Shannon diversity index and Simpson index, respectively and presented with 84% confidence intervals. The
354 solid line represents the rarefied values, and the dashed line represents the extrapolated values and is extended to double the
355 reference sample (empirical value, solid circle), following Chao et al (2014). Panels A, D and G show the diversity accumulation
356 of all samples from all habitats. Panels C, F and I are curves of the same data as B, E and H but separated for clarity.

357 *Changes in community composition across the landscape*

358 Only three taxa were not detected in the twice logged forest: small toothed palm civet
 359 (*Arctogalidia trivirgata*), banded civet (*Hemigalus derbyanus*), and the unidentified felid
 360 species (Figure 4). Bearded pigs, muntjacs and sambar deer were detected in all habitat
 361 types. The most diverse family detected was the Viverridae with four different genera
 362 recorded, and overall the most abundant detections were of bearded pig (*Sus barbatus*),
 363 followed by sambar deer (*Rusa unicolor*). Six of the taxa were rarely detected, with a single
 364 occurrence (including species of conservation concern as designated by the IUCN Red List
 365 (IUCN, 2020): Asian elephant (*Elephas maximus*, Endangered), Sunda pangolin (*Manis*
 366 *javanica*, Critically Endangered), and masked palm civet (*Paguma larvata*, Least Concern),
 367 all which were detected only in the twice logged forest, and the small-toothed palm civet
 368 (*Arctogalidia trivirgata*, Least Concern) which was detected only once in the old growth
 369 forest (Figure 4). There was a single detection of the banded palm civet (*Hemigalus*
 370 *derbyanus*) which is listed as Near Threatened (NT) by the IUCN red list in heavily logged
 371 forest.

372

373 **Figure 4.** Shows the number of detections of each genus across the three different habitat
 374 types. Felidae is the only assignment at family level.

375 The NMDS ordination based on the Chao dissimilarity coefficients converged with a stress
376 value of 0.1 on two axes ($k = 2$) and 0.04 on three axes ($k = 3$). Visualising axis 2 versus axis
377 3 revealed a clear separation of communities detected in twice logged and heavily logged
378 forest (Figure 5). The PERMANOVA test showed a significant effect of habitat type ($DF =$
379 $2/56$, $R^2 = 0.12$, $F = 3.81$, $p < 0.01$).

380

381 **Figure 5.** Non-metric multidimensional scaling (NMDS) ordination based on genera
382 presence/absence using the Chao dissimilarity index showing the difference in community
383 structure between sampling sites. Displaying the second and third axis. The ellipses show
384 the 95% confidence area around the habitat type group centroids.

385 *Effects of habitat and microclimate on mammal diversity*

386 Of all the richness models ($n = 8$, no interactions considered), six models had a cumulative
387 weight of > 0.95 . The null model and the mean temperature model accounted for over half of
388 the cumulative weight of the final model set (Table 3). Mean temperature was also retained
389 in a higher proportion of the total models compared to the other variables (mean
390 temperature = 0.35, mean VPD = 0.23, habitat = 0.15). However, no model can be considered
391 a better fit, or no term can be considered to have greater importance, given that the null
392 model (including the offset term only) was retained in the final set of models. Therefore, the
393 rate of detection appears to be driven mainly by the number of leeches collected.

394

395 When comparing community diversity using the Hill number where $q = 1$, we found that the
396 model with the lowest AIC was the one that included temperature and habitat type, followed
397 by the null model with only the offset term included. These two models account for almost
398 half of the cumulative weight = 0.49 (Table 3). Mean temperature had the highest proportion
399 of retention in the models (0.63), followed by habitat (0.47) and then mean VPD (0.26). As
400 with the richness models because the null model has been retained as one of the models
401 within the AIC criteria (Table 3), this indicates that no conclusions can be drawn on the
402 influence of the variables in the model.

403

Table 3. Model comparison for models which are within 0.95% of the cumulative AIC weight of the total model set, for two diversity metrics, $q = 0$ and $q = 2$. Models are in order of descending ΔAIC for each order of q . AICw is the cumulative AIC weight of the models. The weighted proportion of retention for each of the main terms is given in parentheses. This is sum of the cumulative weight of each model the term appears, divided by the maximum weight, as a summary of its relative importance. All models include the offset term of total number of leeches per pool. The final model * for $q = 1$ is included as the last model over 0.95 cumulative weight.

| Model | ΔAIC | AICw |
|--|--------------|--------|
| Diversity order of $q = 0$ | | |
| Null | 0 | 0.40 |
| Mean temperature (0.35) | 1.47 | 0.59 |
| Mean VPD (0.23) | 1.99 | 0.73 |
| Habitat (0.15) | 3.37 | 0.81 |
| Mean temperature + mean VPD | 3.40 | 0.88 |
| Mean temperature + habitat | 3.64 | 0.94 |
| Diversity order of $q = 1$ | | |
| Mean temperature + habitat | 0 | 0.28 |
| Null | 0.56 | 0.49 |
| Mean temperature (0.63) | 1.18 | 0.64 |
| Mean temperature + mean VPD + habitat | 1.79 | 0.76 |
| Mean VPD (0.26) | 2.56 | 0.83 |
| Habitat (0.47) | 2.94 | 0.90 |
| Mean temperature + mean VPD | 3.04 | 0.958* |

404

405 Discussion

406 We show that iDNA-based surveys can successfully identify differences in mammal
407 communities in forest habitats of varying quality. From our 57 pooled samples of 557 leeches
408 we identified at least 14 mammalian genera, representing 10 families. The highest
409 abundance of detections was from large ungulates, specifically, the bearded pig, sambar deer
410 and muntjac (order Cetartiodactyla), followed by detections of the genus *Hystrix*,
411 representing either the Malay porcupine (*Hystrix brachyura*) or the thick-spined porcupine
412 (*Hystrix crassispinis*). Camera trapping studies at other sites in Sabah have also recorded
413 these taxa at high abundances (Bernard et al., 2013, 2014). The highest number of genera (n
414 = 4) for a single family was detected for the Viverridae (order Carnivora), representing half
415 of the species diversity from this taxon in Sabah (Payne & Francis, 1985). In addition to these
416 detections of common species, we also detected a number of less commonly recorded
417 species, including the pangolin and sun bear.

418
419 The importance of leeches in the detection of rare species is supported by a recent study that
420 combined camera trapping and iDNA sampling in Vietnam, where leeches increased
421 detections records for rare species (Marbled cat, Owston's civet and Asian black bear)
422 compared to cameras alone (Tilker et al., 2020). Although we did not record a complete
423 catalogue of mammals known to occupy our study area, we did detect the majority of large-
424 bodied, non-volant mammals. However, we only detected one genus of diurnal primate
425 (macaque), despite the fact that several occur in the area. The presence of macaques in our
426 sample might reflect the fact they spend more time on the ground than do gibbons, leaf-
427 monkeys and the orangutan (Hanya, Kanamori, Kuze, Wong, & Bernard, 2020). With the
428 exception of the porcupines, we recorded no rodents or bats, which together account for the
429 largest components of mammalian biodiversity in Bornean rainforests. This trapping bias
430 illustrates the limitation of leeches as iDNA samplers, and likely reflects their foraging
431 behaviour on the ground or in the understory. Thus combining leeches with other
432 invertebrate samplers, or with complementary trapping methods, may help to obtain more
433 complete taxonomic coverage (i.e. dipteran flies, Gogarten et al., 2019; Hoffmann et al.,
434 2018).

435

436 **Habitat differences in mammalian diversity**

437 When looking at leech pools from all habitats, the accumulation of genera approached an
438 asymptote for higher orders of q , equivalent to Shannon's diversity index and the Simpson
439 index. However, for $q = 0$, species richness, the curve did not reach a plateau, indicating that
440 more sampling is needed. This under-sampling appears to be driven by the old growth
441 habitat, for which actual species richness is expected to be much higher. Interestingly, we
442 found some evidence that samples from the old growth forest contained lower levels of
443 taxonomic diversity compared to the other two habitat types. This finding may reflect
444 elevated numbers of generalist species in degraded habitats, and broadly agrees with
445 previous findings. Wearn et al., (2017), for example, used camera trap data to characterise
446 and compare diversity of Bornean mammal guilds between old growth and logged forest,
447 and found consistently higher levels of diversity in the latter. Despite this, the lower sampling
448 effort in the old growth sites in our study means that any conclusions regarding this habitat
449 type must be considered tentative.

450

451 Within the two categories of degraded forest, we found higher alpha diversity as measured
452 by species richness in the twice logged forest than in the more heavily logged forest. At
453 higher orders of q , however, we found much greater overlap between these two habitats.
454 Overall, the accumulation of diversity was seen to reach an asymptote at $q = 2$, consistent
455 with the expectation that the reciprocal of the Simpson index is suited to cases of near-
456 complete sampling. Taken together, these results imply that the differences in alpha
457 diversity between forests with different logging histories are probably driven by small
458 numbers of uncommon species, and that when the number and evenness of detections is
459 considered (i.e. higher orders of q), then the overall diversity becomes more similar between
460 these habitats. Thus, the use of higher orders of q appear to be less sensitive to biases from
461 sampling effects due to the fact they are dominated by the incidence of commonly occurring
462 species.

463

464 Multiple previous studies from Borneo have shown the importance of logged forests within
465 modified landscapes for supporting biodiversity. Indeed once-logged forests appear to retain
466 much of the mammal species richness of primary forests (Putz et al., 2012), although

467 subsequent analyses have revealed effects on community composition (Costantini, Edwards,
468 & Simons, 2016; Gray et al., 2014; Wearn et al., 2017). Here we show that iDNA-based
469 sampling can recover differences in community composition, with species of conservation
470 concern (e.g. pangolin) only recorded in the better-quality habitat. However, unlike these
471 earlier studies, we were unable to test for species richness declines in plantations and/or
472 pastures, due to the absence of leeches in these relatively arid environments, which also
473 represent the end points of forest degradation (e.g. Edwards, Tobias, Sheil, Meijaard, &
474 Laurance, 2014).

475

476 **Effect of microclimate on detection of diversity**

477 Our models of richness and Shannon's diversity index showed no clear effect of microclimate.
478 In all cases, the null model, which only includes the total number of leeches collected as an
479 offset, was retained in the final set of models, and therefore cannot be excluded as the best
480 description of the data. This result suggests there is a strong effect of leech abundance, and
481 that this drives subsequent numbers of detections. Thus if microclimate-mediated responses
482 do drive differences across habitats, they appear to mainly affect leech density rather than
483 either their feeding preferences or success. Nonetheless, a lack of clear effect of temperature
484 and humidity was somewhat surprising given the mounting evidence that microclimate and
485 microrefugia play important roles in tropical ecosystems (Hardwick et al., 2015; Jucker et al.,
486 2018; Senior, Hill, Benedick, & Edwards, 2018). However, we cannot completely rule out an
487 effect of temperature on detection given that this variable showed the highest proportion of
488 retention across models of species richness. Ultimately, we suggest that microclimate effects
489 on iDNA-based detections need to be tested in a larger dataset that includes better coverage
490 of old growth habitat.

491

492 **Other considerations for iDNA studies**

493 With increasing numbers of studies using invertebrate samplers to assay vertebrate
494 diversity, there is a growing appreciation of the importance of several aspects of study
495 design, especially with respect to the choice of sampler, laboratory procedures, and
496 statistical frameworks. First, the choice of sample should consider not only detection biases
497 introduced by habitat or microclimate but should also consider potential species differences.

498 Previously, for example, we showed that the tiger leech *Haemadipsa picta* yielded more
499 mammal diversity than did the brown leech, *H. zeylanica*, probably as a result of the former
500 species' greater tendency for arboreal foraging, and wider distribution (Drinkwater et al.,
501 2019). This species difference in detection probability has also been supported by Abrams
502 et al., (2019). Most iDNA studies to date have also treated leeches and other invertebrates as
503 passive samplers, whereas these taxa may exhibit some degree of active prey choice.
504 Evidence for prey selection was previously suggested for the Japanese blood feeding leech
505 (*Haemadipsa japonica*), where mammals seen on camera traps differed from those detected
506 by iDNA (Hanya et al., 2019). Here the authors concluded that, due to apparent non-passive
507 foraging, this leech species might be a poor choice of sampler for generating a
508 comprehensive biodiversity inventory (Hanya et al., 2019). More work is needed to
509 determine if Bornean leeches also exhibit active prey choice.

510
511 Regarding laboratory procedures, rates of detection in iDNA studies will be heavily
512 influenced by methodological choices, which in turn will depend on the research question
513 (Alberdi et al., 2017). For example, the use of pooling to increase throughput is particularly
514 useful in large cross-continental studies (e.g. Schnell et al., 2018; Tessler et al., 2018)
515 whereas analysing individual leeches separately has been employed in site specific studies
516 where resolution is more important (e.g. Schnell, Thomsen, Wilkinson, Rasmussen, et al.,
517 2012; Weiskopf et al., 2017). In our study, pooling individual leech DNA extracts together
518 increased the scale of our analysis, yet at the same time prevented us from relating mammals
519 to the exact location and timing of individual leech captures. This may be an important factor
520 in single species driven studies, or in the detection of rare species, the most famous example
521 being the development of leech-based surveys for the detection of the saola, *Pseudoryx*
522 *nghetinhensis*, in Vietnam (The Saola Working Group, 2020; WWF, 2013). The common
523 approach of pooling samples may also lead to the masking of DNA templates of rare species
524 by those of common species, such as the bearded pig in our study (also see Pompanon et al.,
525 2012).

526
527 An additional methodological consideration that is likely to have an important impact on
528 detections is the choice and number of DNA markers. Although the 16S marker used in our

529 study commonly features in iDNA work, it cannot resolve among some closely related taxa,
530 such as congeneric species within the Felidae family. Thus additional markers would almost
531 certainly allow us to resolve more species within our sample. For example, in another recent
532 iDNA-based survey of mammals conducted in Sabah, Abrams et al. (2019) recorded just
533 three additional genera ($n = 18$) from nearly double the number of leeches ($n = 1532$);
534 however, their use of three mitochondrial markers (16S, 12S and *CytB*) allowed them
535 identify 22 species (Abrams, Hörig, Brozovic, Axtner, Crampton-Platt, Mohamed, Wong,
536 Sollmann, Yu, Wilting, et al., 2019). Thus, where possible, future studies should aim to use
537 multiple markers to increase taxonomic resolution, as also recommended by Axtner et al.,
538 (2019), who proposed new laboratory workflow that included the use of three mitochondrial
539 markers alongside multiple replicates.

540
541 Finally, measures of diversity and habitat effects from iDNA-based monitoring will be
542 influenced by statistical approaches, including the choice of diversity metrics and models,
543 for example Hill numbers (Chao et al., 2014). This framework has also been developed
544 specifically for molecular data from OTU-based metabarcoding studies (Alberdi & Gilbert,
545 2019). Recently, statistical frameworks that account for imperfect detections, notably
546 occupancy models, have also been applied to environmental DNA data (Dorazio & Erickson,
547 2018; Griffin, Matechou, Buxton, Bormpoudakis, & Griffiths, 2019; Hunter et al., 2015;
548 Schmidt, Kéry, Ursenbacher, Hyman, & Collins, 2013). Abrams et al., (2019) applied single-
549 season occupancy models to leech iDNA and camera trap data, and found comparable
550 probabilities for mammals across these techniques. The incorporation of occupancy-based
551 methods has also been applied in the context of poaching and defaunation for identifying
552 priority conservation areas in Vietnam, again demonstrating the power of a combined
553 approach (Tilker et al., 2020). Furthermore, Broms, Hooten, & Fitzpatrick (2015) have
554 developed an extension of the occupancy modelling framework which utilises Hill numbers
555 of diversity.

556
557 In our study, by using pooled samples of a single leech species to generate Hill numbers of
558 taxonomic diversity, we find differences across forest types with different logging histories.
559 Therefore, although leeches cannot provide an exhaustive catalogue of the mammals present

560 at a given site, leech iDNA is nevertheless still capable of assaying a representative
561 mammalian community that includes rare species. Advances in methods and sequencing
562 technologies will be needed to further enhance accuracy and confidence in iDNA detections.
563 Additionally, gaining a deeper understanding of leech ecology and integrating more
564 sophisticated models will be key to the wider uptake of such methods in practice.
565 Nevertheless, our findings showcase the potential for using iDNA based sampling methods
566 for biodiversity surveys in degraded and pristine tropical forests.

567

568 **Acknowledgements**

569 We thank the Sabah Biodiversity Council for permission to conduct fieldwork in Sabah
570 samples (access and export permits for 2016/2017 - JKM/MBS.1000-2/2 (34)
571 JKM/MBS.1000-2/3 JLD.2 (107) and JKM/MBS.1000-2/3 JLD.3 (44)). We also thank the
572 Danum Valley Conservation Area for allowing permission to conduct research
573 (YS/DVMC/2016/253) and Yayasan Sabah, the Sabah Forestry Department, and Benta
574 Wawasan, for access to field sites. For assistance in the field, we thank all LOMBOK research
575 assistants, the Stability of Altered Forest Ecosystems (SAFE) project, Sime Darby, and the
576 South East Asian Rainforest Research Partnership (SEARRP). For help in the laboratory, we
577 are grateful to staff at the Bart's and the London Genome Centre (Queen Mary University of
578 London) and the Danish National High-Throughput Sequencing Centre (University of
579 Copenhagen). For advice on laboratory and analytical procedures, we thank Ida Bærholm
580 Schnell, Kristine Bohmann and Martin Nielsen. We thank Joseph Williamson and Jan
581 Gogarten for advice on analyses, and Mark Siddall, Jan Gogarten, Andreas Wilting and two
582 anonymous reviewers for helpful comments on an earlier version of the manuscript. This
583 study was funded by Natural Environment Research Council's Human Modified Tropical
584 Forests (HTMF) Programme (NE/K016148/1), with additional support from a Study Abroad
585 Studentship awarded to RD by The Leverhulme Trust (SAS- 2016-100). TJ was supported by
586 a UK NERC Independent Research Fellowship (Grant No. NE/S01537X/1).

A. Island of Borneo

B. The SAFE Project sites

Estimated diversity

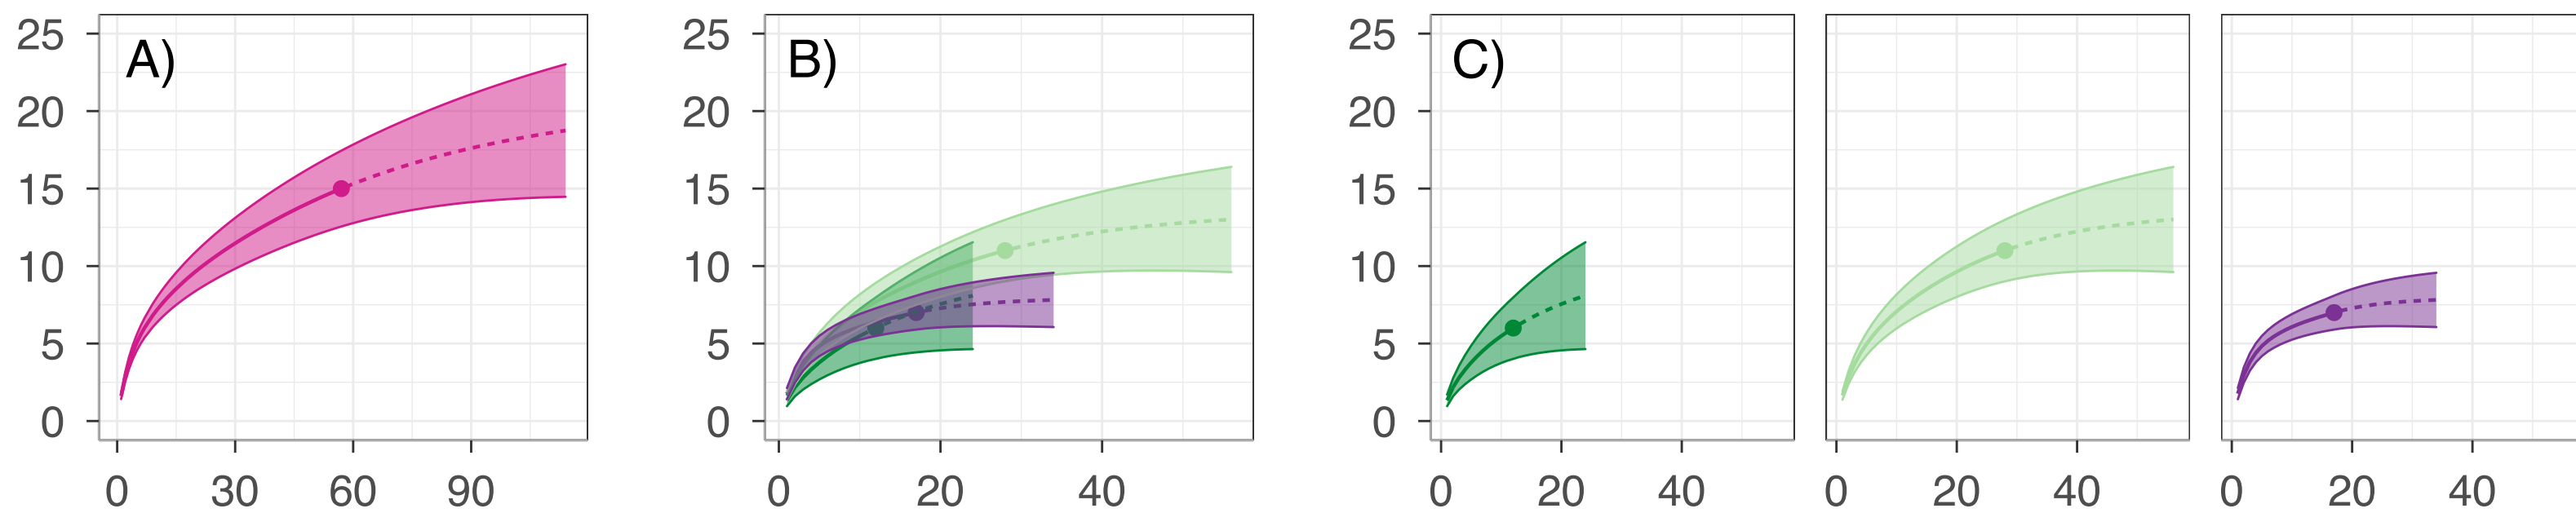

Rarefied diversity

- Old growth
- Twice-logged
- Heavily-logged

 $q = 0$  $q = 1$  $q = 2$ 

Taxonomic diversity

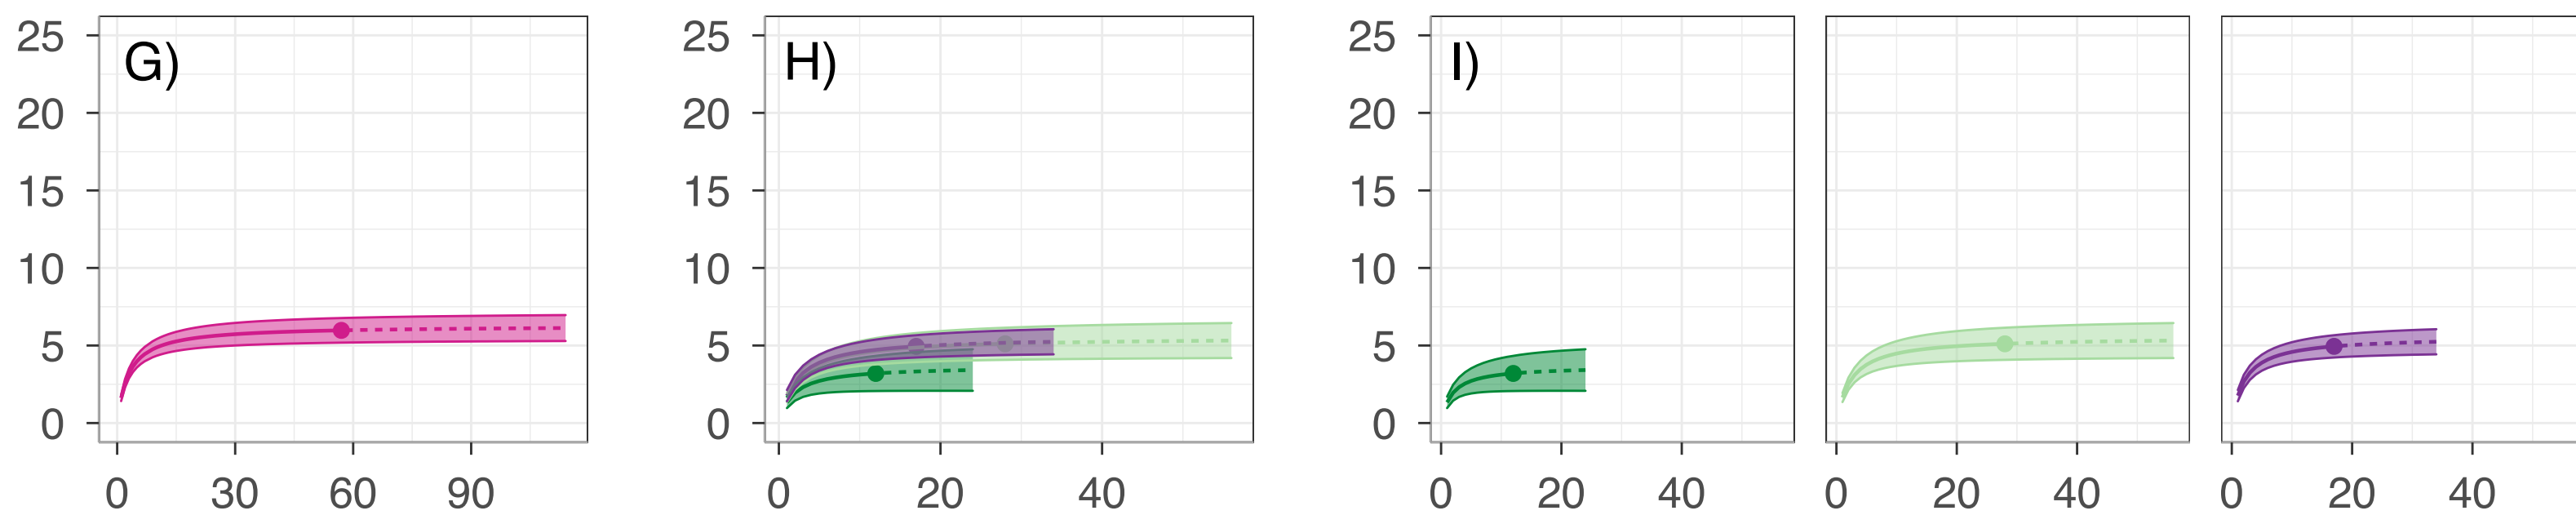

Diversity where $q = 0$

Diversity where $q = 1$

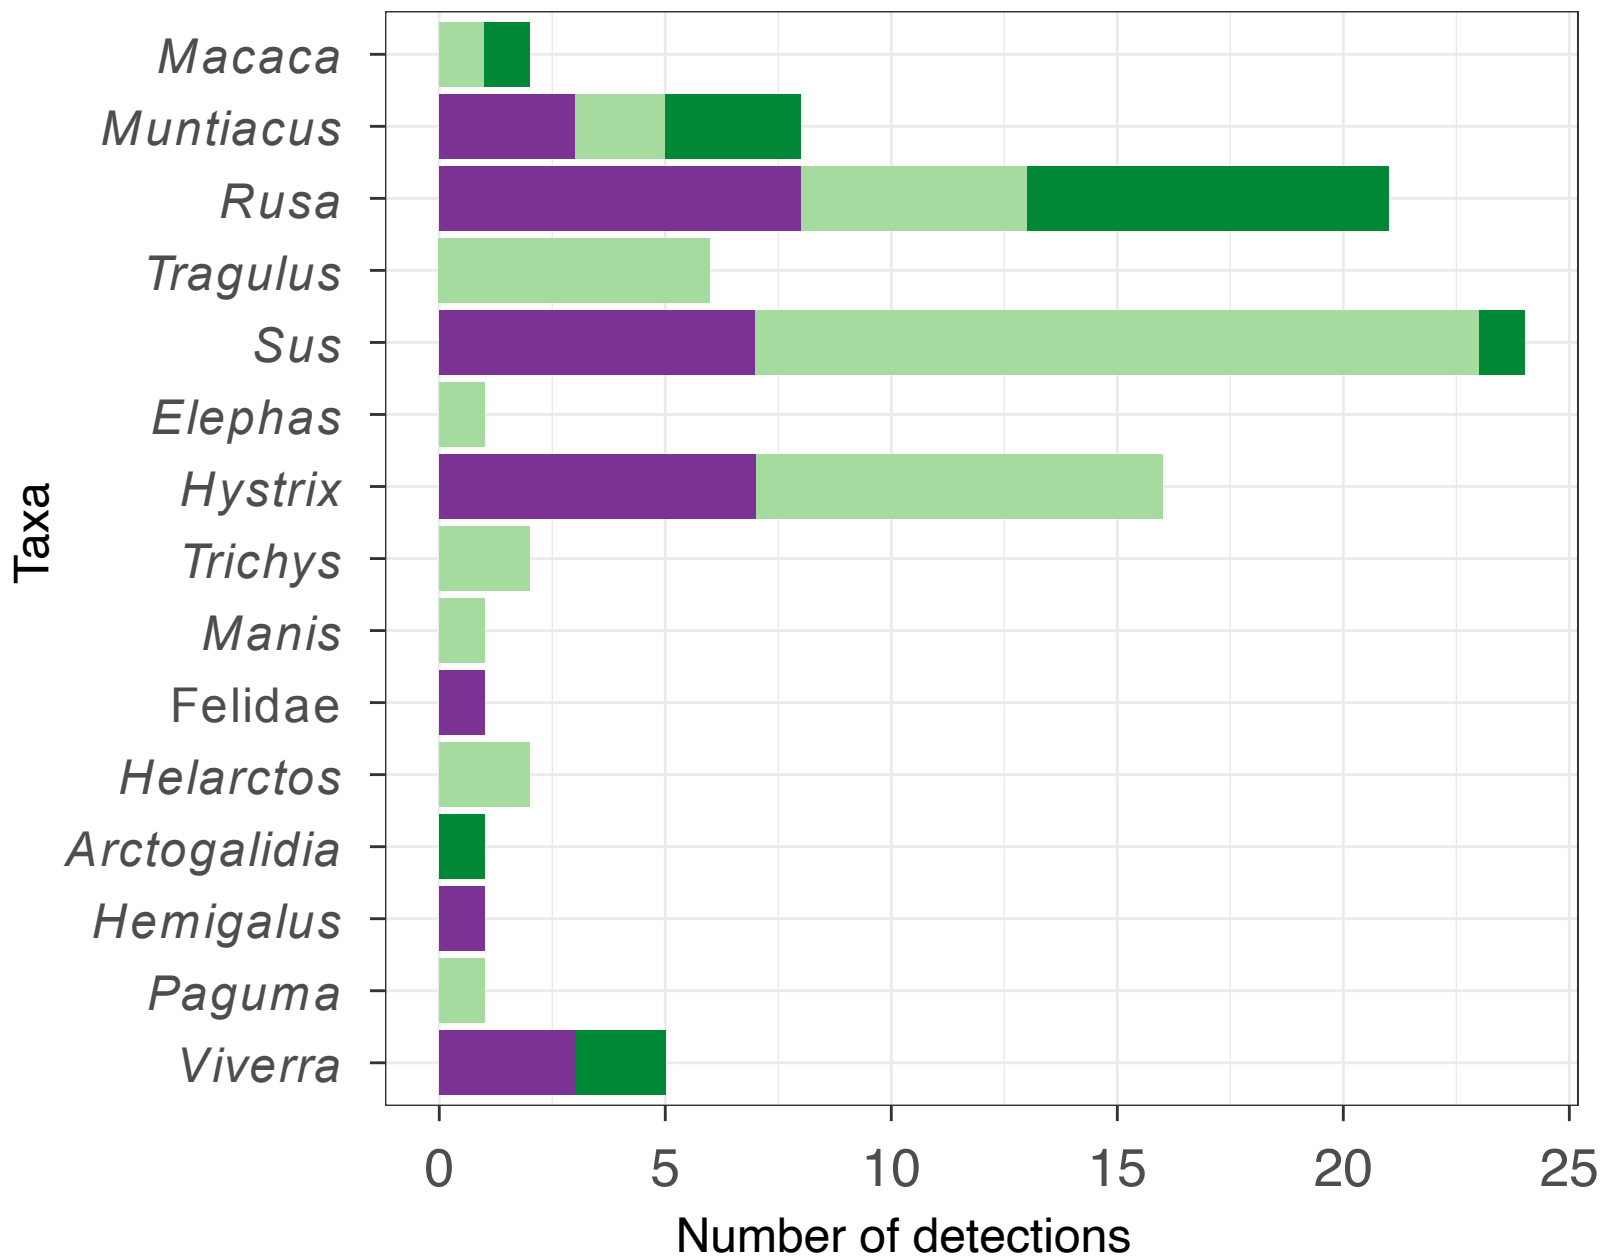

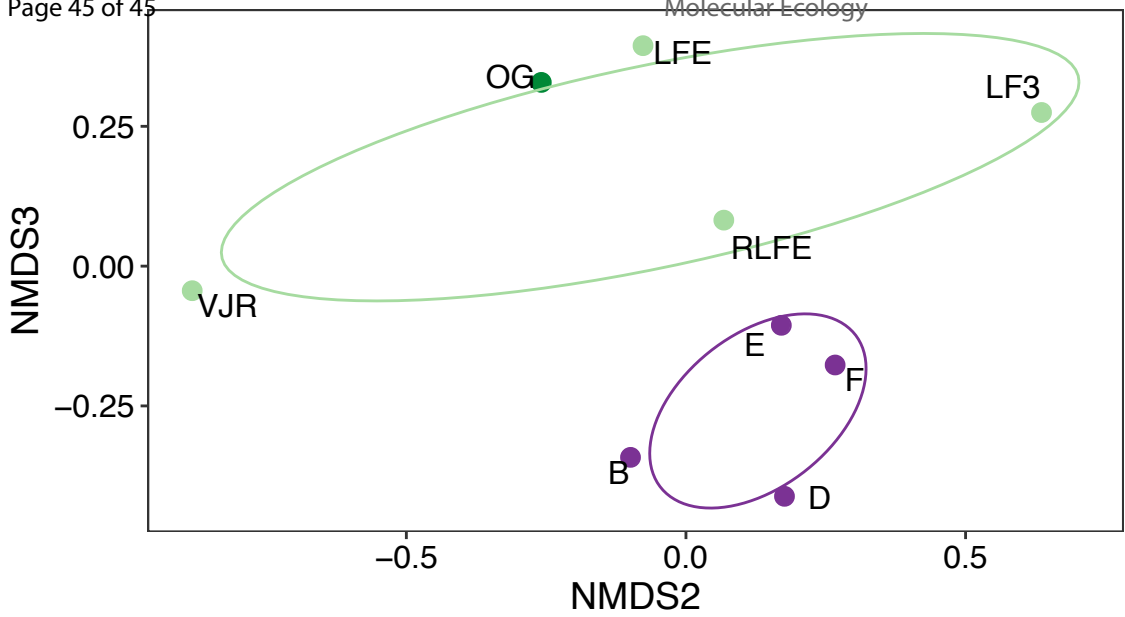

Diversity where $q = 2$

Number of leech samples

Heavily logged Twice logged Old Growth

- Old growth
- Twice logged
- Heavily logged
