

Reply to Rafael Galupa: Discussing the role of Lppnx in the complexity of the X controlling element, Xce

Andreas Hierholzer^{a,1}, Andrea Cerase^b , and Phil Avner^{a,2}

Rafael Galupa in his letter to PNAS (1) questions whether the sequence *Lppnx* we described in our publication (2) is identical to *Linx* (3). We would like to clarify that our caution in stating that *Lppnx* and *Linx* are the same long non-coding RNA (lncRNA) stems from the existence of multiple alternatively spliced transcripts in this region and from the complexity of the X controlling element (Xce). We believe the functional identity of the two lncRNAs needs to be systematically established before any conclusive statement. Our discussion of this topic reflects this point of view (2).

The focus of our PNAS article is the putative relationship between different *Lppnx* alleles and the Xce locus defined by Cattanach. The starting point of our investigation is the quest to identify the key element of the Xce responsible for the skewed X inactivation when different mouse strains are crossed (4). This is a very important and yet little understood aspect of the X inactivation process that bears important consequences for understanding the unequal penetrance of various X-linked human diseases. In this light, our discovery that OCT-4 and other pluripotency factors associate with *Lppnx* RNA is very exciting and offers a concrete starting point to address the molecular basis of different Xce alleles from different strains. For example, different splice variants of *Lppnx* RNA could bind differential amount of OCT-4.

One of the points of Rafael Galupa's letter is our divergence of opinions regarding the role of *Lppnx* RNA in the repression of Xist. The *Lppnx* allele in P_{gk1a} ES cells (carrying different Xce alleles) carries a higher amount of promoter-bound OCT-4 than in 129Sv. Yet, deleting the promoter region in both P_{gk1a} embryos and ES cells results in a much weaker phenotype than in 129Sv. If the region functions purely as a *cis*-regulatory element, as favored by Galupa et al., one would expect the opposite.

We identified Xist-intron1 (XI1) as a possible *Lppnx* target, providing a pool of pluripotency factors to the region (2). It has previously been shown that XI1 deletion on a hybrid embryonic stem (ES) cell background led to preferential XCI from the XI1 deleted chromosome (5). This may indicate that XI1 influences the choice of the X to be inactivated, similarly to *Lppnx* as noted in our results. That XI1 is a putative downstream target of *Lppnx* is indicated as XI1 deletion rescues the *Lppnx* phenotype (2). Finally, these data do not show that "a positive skewer rescues a negative skewer or vice versa" as stated in Galupa's letter since both *Lppnx* and XI1 act in the same direction.

Our publication does not aim to exclude a role for *Linx* as a genomic regulator or to exclude the possibility that both the lncRNA *Lppnx* and *cis*-regulatory elements in the *Linx* locus might act synergistically in the repression of Xist and in XCI. In our opinion, however, we present more than enough evidence to suggest that Xce function involves more than the *Linx* locus as a *cis*-regulator and present enriching data as to the mechanisms underlying the action of the Xce locus.
